

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

### Usage guidelines

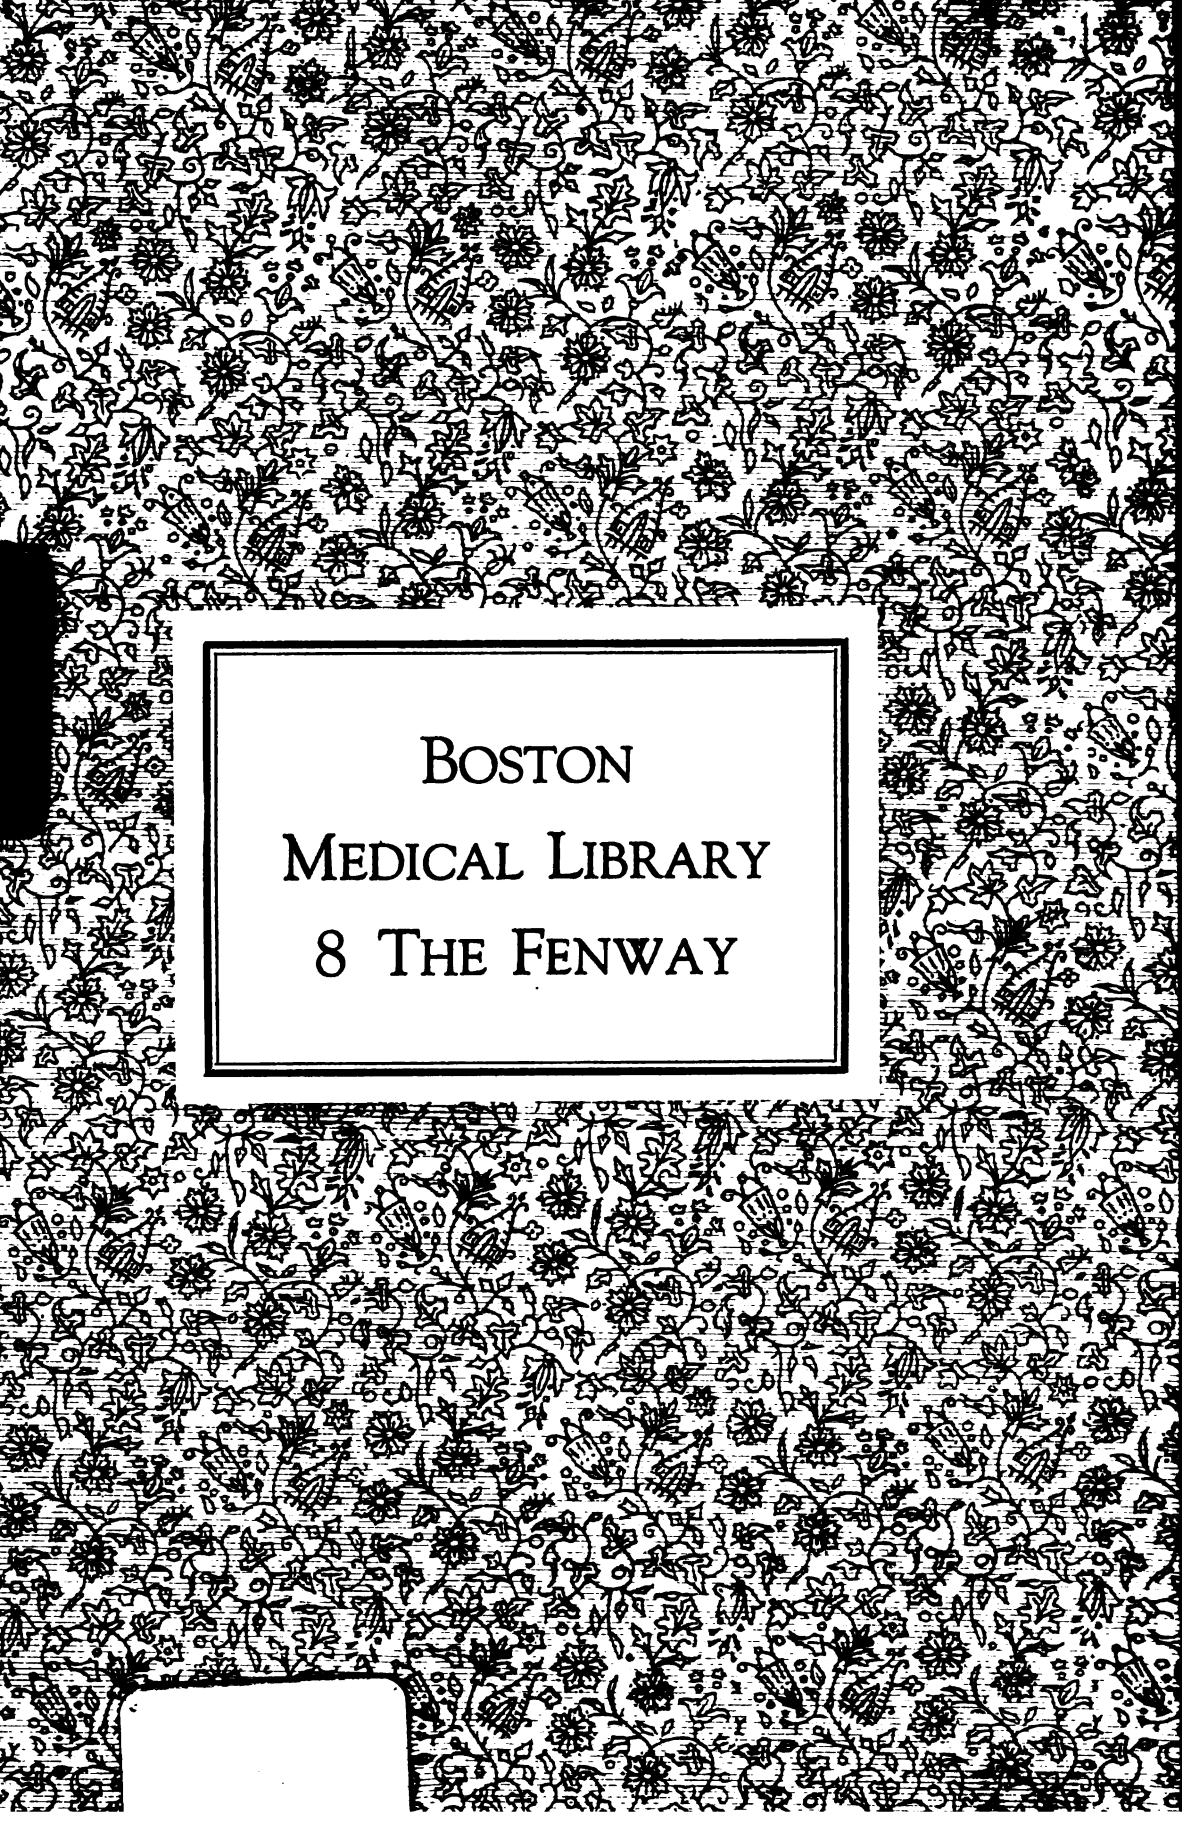

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

### About Google Book Search

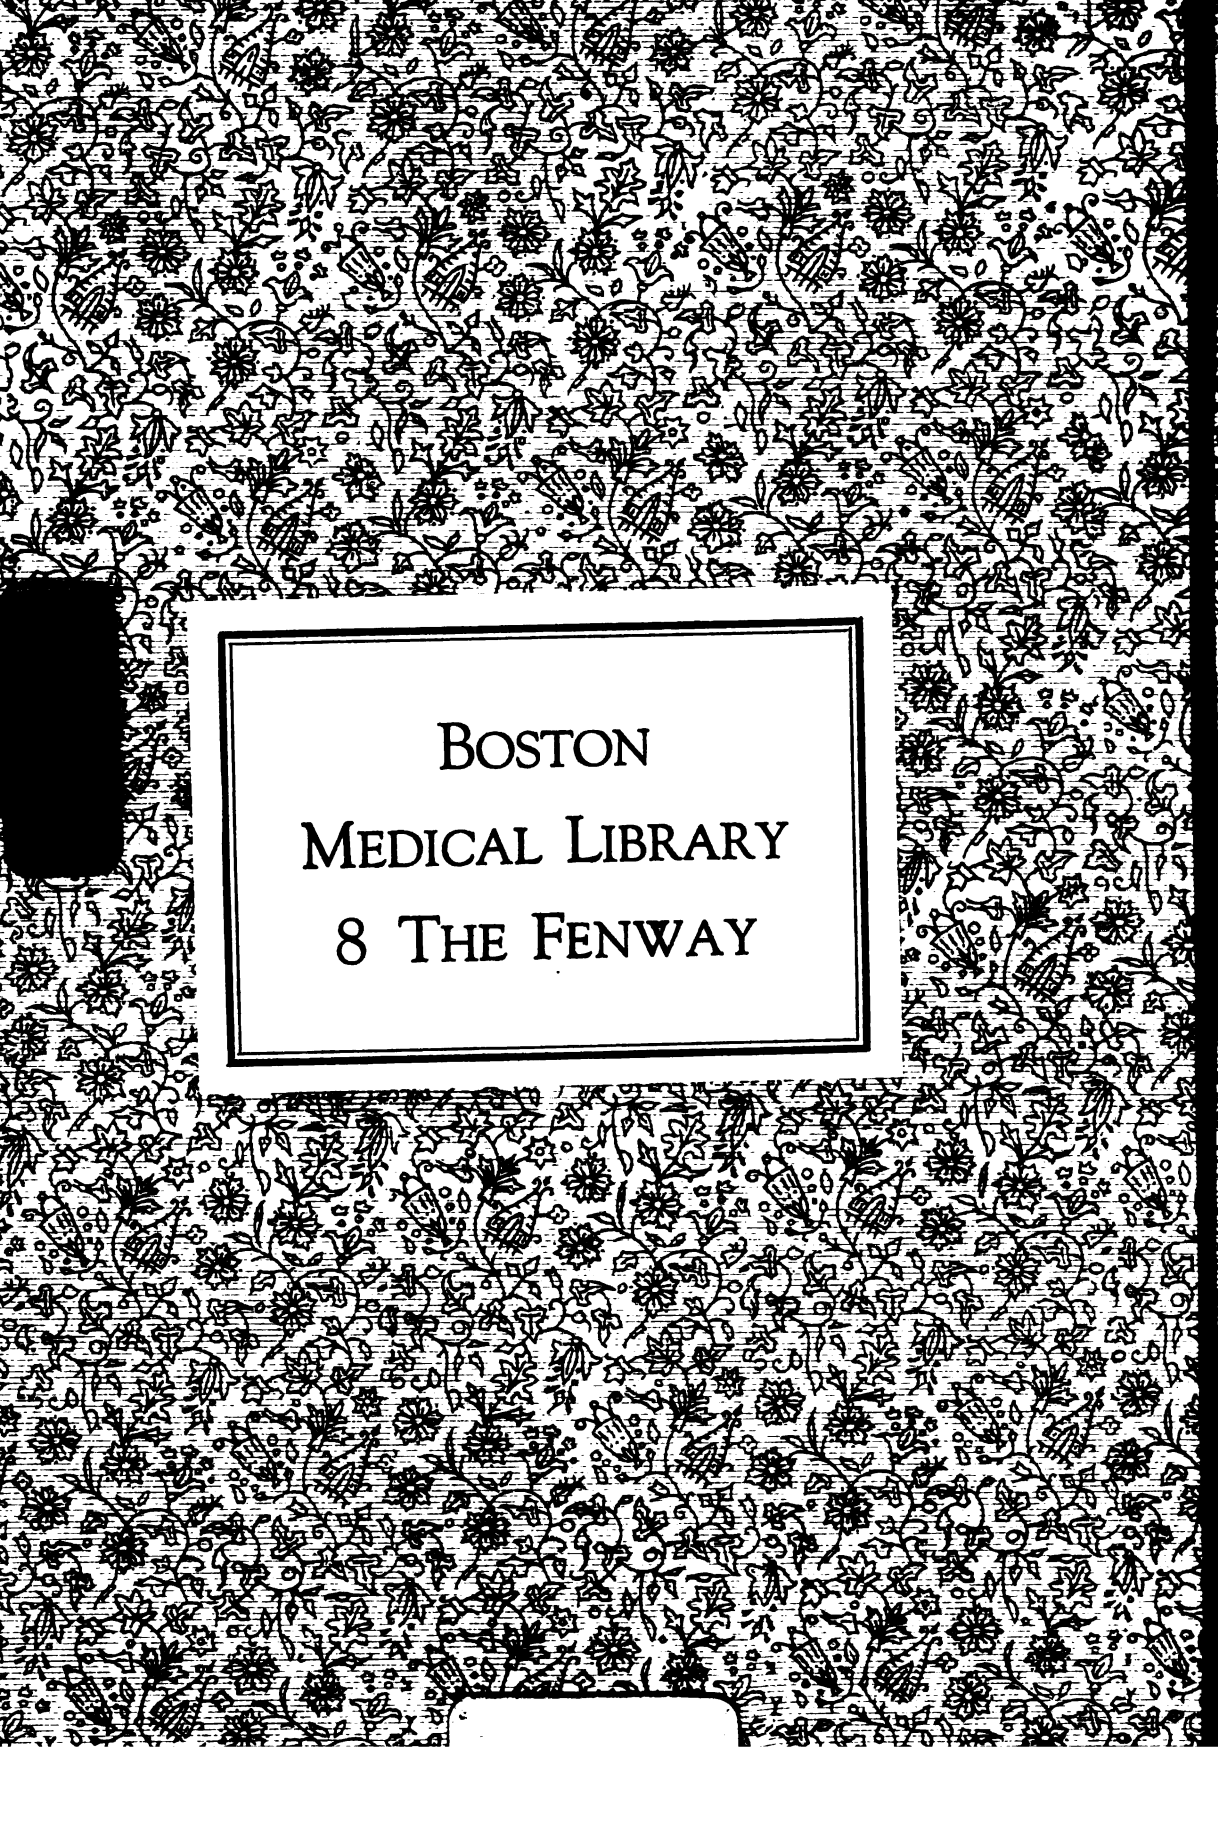

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

### THE SURGICAL TREATMENT OF POTT'S DISEASE.\*

READ BEFORE THE ORTHOPÆDIC SECTION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, OCTOBER 20, 1893.

By W. W. KEEN, M.D.,

Professor of Principles of Surgery and of Clinical Surgery in the Jefferson Medical College.

THE first laminectomy for Pott's disease seems to have been done by Jackson, of Sheffield (*Brit. Med. Journ.*, 1883, i. p. 812); but the modern surgery of Pott's disease really dates from the operation of Macewen (*Lancet*,

1885, i. 881), when he operated on a case of paraplegia with incontinence of urine and feces, due to a connective-tissue tumor at the seat of angular curvature of the spine. In this boy, nine years of age, between the theca and the bone was found a fibrous neoplasm one-eighth of an inch in thickness, firmly attached to the theca and covering two-thirds of its circumference. After this was dissected away, the cord was able to expand backward, and pulsation, which had been absent, showed itself, especially opposite the fifth dorsal vertebra. Twenty-four hours after the removal of the pressure the limbs had lost their livid color and were warm; the spastic rigidity was greatly lessened; the perception of tickling the soles had returned and that of touch was improved. Movement was first observed eight days later, and soon after this he had perfect

\* The first part of this paper is part of a paper on the "Surgery of the Spine" in the supplementary volume of Buck's "Reference Hand-Book of the Medical Sciences."

control over the sphincters. After six months he was able to go about without support. Five years afterwards he could walk three miles; attended school regularly, joining in all the games, including even foot-ball.

A second and more aggravated case (*Brit. Med. Journ.*, 1888, ii. 308), operated on in 1884, showed a slight tumor with organic changes in the cord, which had shrunk to about half its normal dimensions. In ten hours after the operation the limbs had lost their lividity and felt warm. From the fourth day she obtained control over her bladder and rectum; six weeks after the operation she could move her limbs freely; and two months after walked a quarter of a mile and was able to perform light duties in the house.

Three other similar cases were operated on, one of which was successful, but the other two died. Besides these cases, he reported the evacuation of an abscess in the posterior mediastinum, which was pressing on the heart and bronchi. This case was also completely successful.

Another similar and striking illustrative case is reported by Southam (*Brit. Med. Journ.*, 1892, i. 655), in a child three and a half years old, all four extremities being so paralyzed that the patient lay helpless in bed, with incontinence of both urine and feces. In this case, at two operations three months apart, he removed the laminæ from the fourth cervical to the first dorsal vertebra inclusive, and removed a quantity of granulation tissue. But little improvement was noticed for nine months after the second operation; then—a most important point of encouragement—the child began to improve, and when the case was reported two years later could walk without assistance and had control over the sphincters.

The source of the nervous symptoms seems not generally to be the mere curvature of the spine, nor the acute myelitis, but the pressure caused either by fungous masses of granulation tissue over the bodies of the vertebræ by inflammatory swelling, but oftenest by a chronic pachymeningitis, or by the accumulation of pus. For instance, W. Arbuthnot Lane (*Lancet*, 1891, ii. 989) reports eleven cases of Pott's disease in which the compression in all but one was caused by an abscess. In none of these were there any fibrous neoplasms, such as are described by Macewen. In such cases death follows either as the result of pulmonary complications, or more frequently from cystitis and renal complications, bed-sores, pain, sleeplessness, etc. In all of Lane's cases the large amount of disease would have precluded a cure

by ankylosis. He urges, therefore, that "every case of paraplegia due to spinal caries should be operated on with as little delay as possible." In view, however, of published clinical results, especially as shown by Lloyd (*Annals of Surgery*, October, 1892, 289), who has tabulated seventy-five cases of laminectomy for Pott's disease, this opinion seems too sweeping if taken without reservation. Thus, Meyers has reported recovery from paraplegia in fifty-five per cent. of two hundred and eighteen cases, Gibney fifty per cent. in fifty-eight cases, Taylor and Lovett ninety per cent. in nineteen cases, and Sayre ninety per cent. in thirty-eight cases. The views of Burrell and Bullard and Kraske seem to be the more reasonable. "So long as we have reasonable or even moderate chances of recovery without operation," say the former authors, "we do not believe it advisable or justifiable, in the present condition of spinal surgery, to perform so serious an operation as the resection of the laminæ." Kraske's rule for interference is well expressed. "It is necessary before operating to have exhausted all other methods of treatment. I would say interfere when a paralysis of the bladder is established; this is the one symptom which is so serious as to justify everything" (Lloyd). To which Lloyd adds, that "the first sign of degeneration of the cord should indicate immediate operation." It will be especially observed that ordinary cases of mere curvature from Pott's disease are excluded, and only those in which paraplegia with all its dire evils has resulted from the caries should be considered suitable for operation, and then only with the limitations already stated. If there are other tubercular complications it is contraindicated.

It will be observed that the cases above referred to fall into two categories: First, the cases of paraplegia from pressure, either by masses of granulation tissue which may arise from the vertebræ within the spinal canal or from thickening from pachymeningitis,—a thickening which, for instance, in Macewen's case, amounted practically to a tumor so far as pressure on the cord is concerned; secondly, cases of paraplegia as a result of pressure on the cord from abscesses resulting from the breaking down of the granulation tissue. Cases of paraplegia from either of these lesions may be treated by laminectomy, with removal of the neoplasm, the granulation tissue, the pus, the carious bone, etc., by the usual means employed in such cases, provided they fulfil the conditions already mentioned.

Besides these there are many cases of ab-

scasses in Pott's disease in which modern surgery has of late achieved notable improvements in the way of preventing the later lesions of the cord, which may properly be briefly alluded to. Until within a few years surgical interference has been limited to evacuation and drainage of these abscesses at their lowest point,—e.g., at the thigh below Poupert's ligament,—with or without curetting or injection of iodoform in ether or an emulsion of iodoform in olive oil. This left the source of the evil—the carious vertebræ—untouched and also very imperfectly treated the abscess. Mr. Treves, in June, 1884 (*Med.-Chir. Trans.*, vol. lxxvii.), urged the evacuation of psoas abscess in the loin, combined with the removal of the carious and necrosed bone by the usual means employed elsewhere.

This method he has perfected and extended, and at the present time carries it out as follows, which I condense from his "Manual of Operative Surgery" (ii. 731): A vertical incision two and a half inches long is made in the loin, whether it be in lumbar or psoas abscess, in order to reach the spine itself rather than merely to drain the abscess at its lowest point. The centre of this incision is midway between the crest of the ilium and the last rib. It is about two and a half inches from the lumbar spines. The lumbar aponeurosis and the attached muscular fibres of the latissimus dorsi are divided the entire length of the incision, thus exposing the erector spinæ, which is drawn strongly towards the middle line, exposing the middle layer of the lumbar fascia. Through this can readily be felt the transverse process of the third lumbar vertebra. A vertical incision, as near the transverse processes as is convenient, exposes the quadratus lumborum, which here is very thin. The quadratus is divided close to the extremity of the transverse processes, and the incision cautiously enlarged until the muscle is divided to the full extent of the external wound. The abdominal branches of the lumbar arteries may easily be wounded, but care should be exercised to avoid them, as well as the main trunks of the lumbar vessels, by keeping close to the transverse processes and reaching the spine by following them.

The inner edge of the quadratus is overlapped by the psoas muscle, and on dividing the quadratus the psoas is therefore exposed. As the fibres of the two muscles run almost parallel, it is important to observe that the interval between them can be recognized by a thin but distinct layer of fascia, known as the anterior layer of the lumbar fascia. Next, the tendinous fibres of the psoas arising from the

transverse processes having been divided, the finger is introduced beneath the muscle until it reaches the anterior aspect of the bodies of the vertebræ, when the incision can then be enlarged as far as is necessary. All risk of wounding the peritoneum will be avoided by making the incision in the quadratus as near the transverse processes as possible.

When the abscess cavity is well opened, the anterior surface of the spine is examined by the finger. An irrigator is then introduced into the abscess, and it is flushed by many gallons of sublimate solution (1 to 5000). While this is being done, the position of the patient is repeatedly changed, so as to fill and again empty the abscess cavity many times. During the washing out, the finger is introduced into every accessible portion of the abscess, diverticula are opened by it, collections of caseous matter are scraped away with the finger-nail, and in general all the tubercular granulation tissue got rid of as far as possible. The sharp spoon can be used, but, should be used with caution, especially on the anterior wall, which is thin. Mr. Treves thinks a piece of fine Turkish sponge on a long sponge-holder is the best means of removing the granulation tissue, by wiping and scrubbing the inner wall with a rotary movement of the sponge in every part of the abscess and its diverticula. I have found the ordinary gauze sponges equally good; but to accomplish the object in view much time, many sponges, and prolonged and thorough scrubbing, rubbing, and wiping of the interior of the abscess are necessary. When the sponge or gauze is drawn out practically unsoiled, then the cavity can be regarded as prepared for healing. During this process, or as a separate stage, thorough flushing out is again accomplished. Finally, the abscess is wiped dry and the wound closed by a series of silkworm-gut sutures, including the muscular and tendinous structures. Then the ordinary antiseptic dressing is placed over the wound, and I also prefer to place a large abdominal pad over the site of the abscess anteriorly, so as to assist in obliterating the cavity by pressure. "The subsequent treatment," in the words of Mr. Treves, "consists in absolute rest in the recumbent position for a period of months,—a period which may easily be too short, but can hardly be too long." In adults it will probably be over a year; in children somewhat less. If it can be spent in the best hygienic conditions, out of doors, at the sea-side, etc., so much the better.

A second similar operation may be needed, but Mr. Treves states that on no occasion has he had to do a third operation.

Sometimes Mr. Barker's hollow-handled flushing gouge or sharp spoon, which answers so well for bone, can be used also in these abscesses, but must be used with caution.

In the cervical region retro-pharyngeal abscesses are usually accessible through the mouth, and the bone can also be treated by the same route. Burckhardt (*Centralbl. f. Chir.*, 1888, No. 4) has advocated an external incision at the inner border of the sterno-cleido mastoid, reaching the abscess by the inner side of the sheath of the vessels. Chiene, as early as 1877, advocated a similar operation on the outer border of the sterno-cleido mastoid, and Kramér (*Centralbl. f. Chir.*, 1892, No. 12) has successfully carried out Burckhardt's proposed operation with ease. These operations have the advantage, of course, of permitting more thorough antisepsis than the oral route, but the mortality of the latter has been very small. In abscesses in the cervical region, with difficulty accessible by the mouth, however, these methods of operating will probably prove of greater value than that by the mouth.

In the dorsal region, Shafer (*Journal of the American Medical Association*, December 19, 1891, 943) proposed "to incise the soft tissues one inch from the spinous processes, uncover and remove the transverse process of the diseased bone or of the one just below it, and resect the head and neck of the corresponding rib. This permits a large finger to reach the posterolateral angle of the diseased bone, and gives room for the introduction of the curette, sharp spoon, or forceps, and leaves a large space for a drainage-tube. Should it be desired to carry the drainage-tube through the column, the transverse process with the end of the rib of the opposite side can also be removed, when it can readily be passed through."

A somewhat similar method was published four months later by Vincent (*Rev. de Chir.*, April, 1892, 273). In this somewhat elaborate paper he describes three different methods of side-to-side drainage: (1) prevertebral drainage,—that is, in front of the bodies of the vertebrae; (2) premedullary drainage,—that is, in front of the spinal cord and its membranes, in case of the destruction of the bodies; and (3) vertebral trans-somatic drainage, or drainage through the bodies of the vertebrae. In all cases he selects the point of greatest curvature, makes an incision along the external border of the erector spinæ eight to ten centimetres in length, with a transverse incision from the middle of the first and at right angles to it, about five centimetres long. One or two ribs are resected, the intercostal muscles separated, the

pleura and the tissues in the chest are detached by the finger or any blunt instrument, and, following the track of the granulation tissue and the sinuses, we are able finally to pass the drainage-tube from side to side. The method is not essentially different, whether the tube is passed in front of the bodies of the vertebrae or behind them and just in front of the medulla and its membranes. In the latter case great care should be taken not to puncture or otherwise injure the membranes or the cord itself. Only widespread destruction of the bodies of the vertebrae would allow of premedullary drainage.

In vertebral trans-somatic drainage, the earlier steps are precisely the same as before, with the addition that, by means of the curette or perforator or other such instrument, the body of the vertebra is perforated from each side and the drainage-tube carried through the canal so made.

Shafer reports three cases, in one of which the sinuses, excepting one, all healed in two months and in six months after the operation the patient left the hospital, but a year after the operation she died of pulmonary tuberculosis. In the second case, in which the same procedure was used in the cervical region, there was very serious hemorrhage (checked by packing) in the cavity of the body of the fourth cervical, and the disturbance of the vertebral column was such that her neck felt as though it were broken. A jury-mast enabled her to walk about, and she was discharged from the hospital six weeks after the operation. About six months later (the time is indefinite) the jury-mast was laid aside, she could hold her head erect, was engaged about the house and feeling well. In the third case there was caries of the body of the sacrum, with secondary inflammation of the trochanter major. The patient was somewhat more comfortable after the operation, although the prognosis as to his lungs was very bad.

Vincent reports two cases,—one of trans-somato-vertebral drainage and the other of prevertebral drainage. The first made an excellent recovery; the second died.

The conclusion that I should reach as to this somewhat heroic method is very much that of Vincent: "We cannot as yet come to a conclusion in favor of such operative procedures in Pott's disease. All we can say actually is that they have been practised without accident" (?)—and with varying results. The procedure will only be occasionally useful, and great care must be taken to avoid wounding the pleura, the ganglia of the sympathetic, and the spinal nerves. The intercostal arteries are almost in-

evitably injured, and it seems possible that even the vertebral was involved in one of Shafer's cases.

*THE VALUE OF THE COLD BATH IN  
THE TREATMENT OF ASTHENIC  
DISEASES OTHER THAN  
TYPHOID FEVER.*

BRING THE OPENING OF THE DISCUSSION ON THIS SUBJECT  
BEFORE THE SECTION ON THERAPEUTICS OF THE  
PAN-AMERICAN MEDICAL CONGRESS.

BY SIMON BARUCH, M.D.

THE very fact that this subject has been chosen for discussion is a happy augury for rational therapeutics. When I have hitherto referred to the cold bath as a method of treatment for an asthenic disease I have almost invariably been met with the query, "Would not the shock be too depressing to the patient?" The question for discussion here is an evidence of an awakening to the value of the best remedy for asthenic conditions which we have. Instead of defining asthenia, let us take as an example the most typical form we meet, one a temporary, the other a more enduring condition. Surely a woman who has fallen in syncope presents the most complete picture of asthenia. Her pulse is feeble or absent, her respiration is shallow, sensation and motion are practically abolished, the patient's vital powers lie dormant, as it were. What is the treatment which usage has so sanctioned that even lay people constantly resort to it? The application of cold water to the periphery—the face or chest—is the remedy. You are all familiar with the result; the merest tyro in medicine can give its rationale. There is a reflex stimulus to the nerve-centres, a deep inspiration ensues, the wheels of life again are set in motion, color returns to the pallid cheek, the glazed eye brightens, the pulse beats again. The asthenic condition is removed as no other agent can remove it.

Let us take a more frequent asthenic condition. A patient suffering from an infectious disease lies prostrate, with thready pulse, shallow breathing, dull eye, picking at the bed-clothes, subsultus, involuntary defecation. All these remind us that here we have the very climax of asthenia. What shall we do? Will digitalis and strophanthus arouse a heart whose response depends upon these obtunded nerve-centres? Strychnine gives us some, because it stimulates the nerve-centres. But seat such a patient in a shallow warm bath, and pour with some force one or two basins at 75° F. or less over his head and shoulders; rub him gently;

repeat if indicated. The result will astonish those who have not tried it. There is a gasp for breath, the dull eye resumes its lustre, the facial cyanosis yields to a better hue, the pulse becomes slower and less compressible. The wheels of life are again set in motion; not, as in the case of syncope, to remain so, but to again be overbalanced by the toxic blood which supplies the nerve-centres. Again and again this affusion must be repeated. Fear not the so-called shock, for this is just what you want to evoke; it is, when judiciously administered, followed by reaction, and reaction is the great stimulus, greater than all medicinal agents or alcoholic stimulants. These are clinical facts, observations made at the bedside; they are at least as valuable as those made on medicinal agents.

In low forms of scarlatina, when the feeble, rapid, thready pulse and cyanotic appearance of the skin present every feature of asthenia, several dips of the patient into water at 60° to 75° F., followed or accompanied by friction, arouses the feebly-acting heart more quickly and reliably than all other known stimulants.

What is the rationale of the action of cold water in these typical cases of asthenia? Heart-failure stands like a spectre at the bedside, and the physician often labors in vain to banish it. Heart-failure kills; heart-failure is the culmination of asthenia. How does the application of cold to the periphery restore vigor to the drooping heart? Macy, Traube, and others have shown that in these asthenic conditions we have a loss of tone in the smaller vessels, a paresis of the muscular coat and of the elastic tissue which acts the part of muscular coat in the peripheral capillaries. Now, it is a well-known physiological fact that the circulation of the blood depends not only upon the vigorous healthful action of the heart, but also upon the integrity of the arteries and capillaries by whose elastic resiliency the blood is propelled through the finest tubes. Surely the propulsion of a viscid fluid like blood through such fine tubes would be impossible unless the latter were endowed with propulsive power. What results when the latter is lost or in abeyance? The heart must increase its force to overcome an obstruction at points where it formerly received aid. It is pumping against paralyzed vessels; the blood stagnates in the smaller ones, giving rise to hypostatic congestion, and thus is the difficulty increased. No wonder that the heart labors harder, that the pulse-rate increases and its tension is lowered. No wonder that its ganglionic forces are exhausted and that the heart yields at last to the dread pressure upon

its vital forces, which are sapped besides by the toxic blood supplying it. Apply a judicious hydrotherapeutic procedure in such a case; let it be cold affusion, dip, spray, ablution, a bath, but let it be adapted to the case and always accompanied by friction. What is the result? There is a local stimulus to the coats of the superficial vessels; they contract again under the impact of repeated cold wave followed by friction. Their paresis is removed; they again propel the blood as was their wont. The dam is cut, as it were; the blood again flows freely through the terminal vessels; the heart responds to the relief afforded by a slower and more deliberate contraction; we have normal tension and absence of diastolic. At the same time the central nervous system is bathed by cooler blood, blood which is better oxygenated, and thus the cardiac ganglionic centre receives new life at one end, while at the other the labor of propelling the blood is removed. If any one doubts this rationale, let him see the deadly pale skin (except the dusky face) of advanced typhoid redden under this procedure and come out glowing with the roseate hues of health, and he will be convinced; let him see the marbled skin of a low scarlatina brighten up under the friction and bathing and resume its color, and he will no longer doubt. In chronic conditions phthisis offers a good illustration of the effect of hydrotherapy in removing the obvious asthenic conditions.

We have the testimony of Ziemssen, who refers to it as "a remedy of extraordinary value." Indeed, clinical demonstration of the "value of the cold bath in asthenic conditions" is abundant. The Montefiore Home for Incurables receives its supply of patients from other hospitals which decline to retain them on account of their incurability and protracted nature. Here I have had an opportunity of testing this question in a satisfactory manner in cases of phthisis, Bright's disease, diabetes, and a variety of functional and organic nervous diseases which make the institution the Salpêtrière of America. The gradual education of the reactive capacity in these desperate cases and the improvement of the nutrition in many of them offer interesting illustrations of what may be accomplished by the methodical application of water. The annual reports of the institution furnish the details, with which I need not burden you here. I will cite only two cases from private practice that may be of interest. A young man from Kentucky, who had been pronounced phthisical (right apex, first stage) by Dr. Janeway, whose sputum had been referred to the Van-

derbilt Clinic Laboratory to culture bacilli without appetite, emaciating for six months, was treated at the Hydratic Institute from August, 1892, to January, 1893, with the result of sixteen pounds' gain, complete removal of bacilli (examined at the Vanderbilt Laboratory by Dr. Van Giesen seven times). He remained well. His brother is now under treatment for the same (more advanced) trouble, and has gained four pounds in three weeks. A middle-aged lady, who had cervix and perineum operated on by Dr. Ralph Waldo, and who had been bedridden for two years, was advised by Dr. Charles Carroll Lee, called in consultation by Dr. Waldo, to place herself under hydratic treatment. She was carried into the institute by her husband and brother, presenting every manifestation of pronounced neurasthenia of the melancholic type. Her reactive capacity was feeble, but it was gradually raised, until after six months' treatment she asked to be allowed to use a bicycle, so active and strong had she become. She is now in good health.

With these brief histories I may conclude my commendation of the "cold bath in asthenic conditions," acute or chronic.

*THE CLASSES OF INVALIDS MOST BENEFITED AT ATLANTIC CITY.*

READ BEFORE THE CONGRESS OF MEDICO-CLIMATOLOGY IN CHICAGO, JUNE 3, 1893.

BY BOARDMAN REED, M.D., ATLANTIC CITY, N. J.

**N**ERVE exhaustion, or, in popular parlance, nervous prostration, is, in its various forms, the disease most certain to be benefited at Atlantic City. Probably a prolonged sea-voyage or a sojourn at some of the other sea-shore resorts might be equally helpful. I cannot say as to this, but confine myself to a report of facts carefully observed during a residence of more than fifteen years.

Sea air, as exemplified at Atlantic City, is a nerve tonic of the utmost value. Whether the unfortunate victim of an overtaxed nervous system chances to arrive in a rain which confines him to his hotel (as will sometimes happen, especially in the winter or spring), or whether he finds all sunshine and brightness, he—or more often it is she, since the majority of neurasthenics are women—will nearly always begin at once to eat and sleep better. Fine weather, though helpful, is not essential, and most cases will gain even in spite of it. With quickened appetite and sounder sleep come an enriched blood and refreshed nerve-centres.

All vital processes are heightened, and health is usually and often rapidly restored.

True, there are exceptions. Occasionally a nervously-depressed patient, who considers himself merely run down from overwork or other cause, comes to Atlantic City, puts up at one of the best hotels, and sets out to get well by doing as he sees others do, yet fails utterly, returning home after one or two weeks worse, perhaps, than before. There are usually excellent reasons for these failures. One of the most common is the existence of derangements of the stomach or liver, which are suffered to go without proper treatment. Sea air is simply a tonic, —a powerful and effective one in most cases, but still only a tonic and not a corrective of faulty secretions. The patient who has been trying to overcome an increasing debility by forcing larger quantities of food—often, very unsuitable food at that—upon an unwilling, because unhealthy, stomach, with the help, perhaps, of an unaccustomed amount of stimulants, until his tongue has become foul and his entire digestive apparatus on the point of revolting, will not recover by the mere fact of sojourning at any sea-side place. If he has gone on in this way until his urine has become loaded with urates, his joints stiffened, his temper moody and despondent, and his sleep considerably impaired, the sea air, though a most valuable aid in the task of curing, will do next to nothing until the way has been cleared for its proper action by a judicious course of medical treatment instituted either by the physician at home or by some competent local practitioner at the shore after the patient has arrived there. Fortunate is it for the poor neurasthenic if he or she has not let matters drift along until insomnia has developed into a chronic condition and the habit of taking some narcotic drug has become fixed. These are the cases which try the souls of physicians everywhere; but even these will do well and usually recover at Atlantic City, if placed under proper conditions, and especially if they can have the benefit of the Weir Mitchell "rest-cure" (or some modification of it in the less severe cases), under the guidance of a physician and nurse experienced in such special treatment.

Closely allied to neurasthenia is simple atonic dyspepsia, and this rarely fails to respond to the healthy stimulus of the sea air, especially when the diet and exercise have been properly regulated. In the worst cases the aid of medicine, as well as of electricity and massage, is sometimes necessary, but many recover with only the simplest hygienic treatment.

Convalescents from operations, as well as

from fevers or other acute prostrating diseases, will also derive the greatest benefit in nearly all cases from a removal to Atlantic City. Like the nervous cases, these may be expected to gain rapidly even if still confined to their rooms. It is a constant experience to see them taking on flesh and growing stronger at a surprising rate even before it is possible to get them out of doors.

The chronic diseases peculiar to women are generally improved and often markedly so by the invigorating properties of the climate. It tends to bring up the nutrition and nerve tone, thus indirectly relieving congestion and catarrhal states of the pelvic organs. Many of the diseases of childhood are promptly and often remarkably benefited. Persistent cases of summer complaint, as well as nearly every form of malnutrition in children, including especially scrofula, rickets, chronic joint-disease, and chronic bronchitis, find in the atmosphere of the locality a positive and decided adjuvant to other therapeutic resources. In some of these cases the air alone proves rapidly curative without further medical intervention.

In adults, as well as children, chronic bronchitis, chronic pleurisy, and delayed resolution of pneumonic exudations may usually be expected to do well at the same place. In most of such cases it is advisable to persist at the same time with the usual therapeutic measures in order to insure the promptest results.

Anæmia, chlorosis, and struma are benefited by sea air, and, under proper regulations and restrictions, even more markedly so by sea-bathing. But it is highly important to see to it that patients afflicted with these or other maladies shall exercise caution as to the length and frequency of their baths. For some only the very briefest dip in the ocean will be needed to obtain the curative effect or can be safely borne; others should be prohibited altogether from ocean-bathing. At least equal care is needed as to the manner in which the warm or hot sea-water baths are taken. Patients are prone to look upon these as entirely safe for anybody at all times, and to suit their own inclinations as to the temperature of the water and the length of time they remain in it; but no experienced physician need be told that delicate invalids cannot all bear safely a prolonged soak in hot water, whether salt or fresh.

The above-mentioned diseases form only a small part of the many which are benefited by the climate of Atlantic City, but they include those in which I have observed the most marked and constant improvement. Sufferers from asthma and from hay-fever often have an

entire immunity here, but this is by no means always the case. Patients in the early stages of pulmonary phthisis usually do exceedingly well,—quite as well, according to my experience, as they do in the lowlands of the South,—always provided they persist with a rational treatment and can and will spend most of their time out of doors in the open air.

Chronic malarial cases may be cured by a long sojourn at Atlantic City. There is no doubt whatever as to the entire exemption of the place from malaria in the proper sense of that word,—i.e., the miasm which producesague or intermittent fever. The town has an excellent underground sewerage system,—one of the best on the coast,—and is supplied with an abundance of pure and wholesome drinking-water, so that invalids need not incur the dangers which lurk so often in resorts where the sanitation is bad.

## ACTIONS OF DRUGS UPON THE KIDNEY.

ABSTRACT OF TWO LECTURES ON DIURETICS.

By W. C. CAMPBELL,

Professor of Materia Medica and Director of the Pharmacological Laboratory, College of Physicians and Surgeons, Chicago.

GENTLEMEN:—To-day I begin a consideration of a class of drugs called diuretics. These drugs, when given in medicinal doses, increase the activity of the kidneys, increase the secretion of the urine. They not only act upon the kidneys, but also on other organs, and for convenience I will speak first of their action as diuretics, and then afterwards consider each drug separately, giving its composition, pharmaceutical preparations, and other actions. I shall not be content with simply telling you that these drugs increase the flow of urine, but will also, as far as is known, try to explain their mode of action, the different points in the renal mechanism where they act to increase diuresis. While it is true that a large number of pharmacological experiments have been made on the kidney, yet there is comparatively little known about how drugs act on it,—far less than there is about the action of drugs on the motor, respiratory, circulatory, and digestive mechanisms. At present there are many points unsettled, many experiments conflicting, so something I may say later research may prove to be different.

To make myself better understood, I will present the subject in the following order:

1. The action of drugs on the secretion of urine in health.

2. The action of drugs on the reaction of the urine in health.

3. The action of drugs on the composition of the urine in health.

4. The action of drugs on the secretion, reaction, and composition of the urine in disease.

### ON SECRETION OF URINE IN HEALTH.

Before the student can understand the various ways that diuretics act, the various points that the different drugs stimulate or depress to increase the secretion of urine, he must first learn the parts of mechanism and their function; hence I will briefly describe,—

1. The anatomy of the renal mechanism.
2. The physiology of the renal mechanism.
3. The pharmacology of the renal mechanism.

#### *The Anatomy of the Renal Mechanism.*

This mechanism consists of thousands of peculiar glandular structures bound together, and known collectively as the kidney. A complicated nervous mechanism presides over their functional activity. The glandular mechanism as shown in the simple schematic drawing No. 1, where, for simplicity, only one of these structures is represented, is composed of the following five structures: glomeruli, convoluted tubules, constricted tubules, unstriated muscles, and blood-vessels.

1. *The Glomeruli.*—These are situated in the cortex of the kidney, and each consists of a plexus of capillary vessels pushed into the closed capsule, which capsule is the dilated end of the corresponding convoluted tubule. Hence, as shown in Diagram 2, the capsule of the glomerulus consists of two layers, the cavity between which opens into the convoluted tubule. Also notice that the layer covering the capillary plexus is made of cubical cells, while the external layer is formed of flattened cells. This has, as will appear later, an important bearing on the function of the glomerulus.

2. *The Convoluted Tubules.*—These tubules, as shown in Diagram 1, arise from the capsule and pursue a tortuous course, and end in the constricted loops to be described next. They are lined with a single layer of nucleated polyhedral epithelium, as shown in Diagram 3.

3. *The Constricted Tubules.*—These tubules, as seen in Diagrams 1 and 3, are situated in the medullary portion of the kidney, have a much smaller lumen than the convoluted tubules, and are lined with a single layer of flattened epithelium. Notice the difference in the cells of these two different kinds of tubules.

4. *The Unstriated Muscles.*—As shown in Diagram 1, there are unstriated muscle-fibres

ism probably, as shown in Diagram 5, consists of,—

around the constricted loops. Also, in Diagram 4, copied from Kostjurin, they are shown as they appear under the microscope. These

1. Four centres in the medulla oblongata,—the vaso-constrictor, vaso-dilator, secretory, and inhibitory secretory.

fibres are found throughout the kidney, but the only ones that at this place concern us are those around these loops.

5. *The Blood-Vessels.*—As seen in Diagram 1, the afferent vessels convey the blood to the glomeruli; then it passes out by the efferent vessels, and is carried by them to the convoluted tubules. The blood passes through the glomeruli first, then to the tubules. There is an insignificant portion that does not pass through the glomeruli. The nervous mechan-

2. Four sets of fibres passing respectively from these centres by way of the solar and renal plexuses to the kidney.

These nerves, after reaching the kidney, pass to the structures suggested by their names. The vaso-constrictor and vaso-dilator enter the vessel walls. Berkley has shown that they do not enter the capsule and pass to the capillary plexus of the glomerulus. The secretory nerves pass between the epithelial cells of the convoluted tubules. As yet no nerves have been found supplying

the cubical epithelium over the capillary plexus. The recent researches of Berkley in the Patho-

retrograde products, such as urea. In the evolution of these structures the glomerulus was placed above the convoluted tubule, very likely so that the water could wash the urea out of the tubules into the pelvis of the kidney.

logical Laboratory of Johns Hopkins Hospital have shown the terminations of the renal nerves

COPIED FROM A SKETCH OF  
PROP. S. D. KOSTJURIN  
MATTHESI Fig. 4.

as stated above. However, it must not be forgotten that a number of experimenters deny the existence of secretory nerves for the kidney.

#### *The Physiology of the Renal Mechanism.*

The functions of the different parts of the renal mechanism may be briefly stated as follows:

1. The glomeruli excrete water and mineral salts and also certain pathological substances and some foreign materials that have been introduced into the circulation. As the blood circulates through the capillary plexus of the glomerulus, these substances *osmose*, not filtrate, into the capsule cavity, and then pass on into the convoluted tubules. The cubical epithelium, as shown in Diagram 2, excretes these substances by an exosmotic action.

2. The glandular epithelium of the convoluted tubules excretes some water, but mainly the

3. The constricted tubules regulate the amount of urine by their constrictions delaying its exit and permitting some of the water to be reabsorbed. It is probable that the contraction of the unstriated muscle-fibres around the tubules can not only hasten the expulsion of urine by their peristalsis, but also that under certain circumstances they may lessen or increase the size of the constricted loops and affect the quantity of water passing outward.

4. The nervous mechanism regulates the functional activity of the kidney by controlling the blood-supply to the gland, by regulating the activity of the secreting cells, and possibly by acting upon the unstriated muscles around the tubules. It is very probable that these unstriated muscles are supplied with nerves. No experiments have been made with regard to whether drugs acting upon unstriated muscles can in this way affect diuresis.

#### *The Pharmacology of the Renal Mechanism.*

In presenting this I will,—

1. Enumerate the various points where a drug may act;
2. Describe the possible ways in which drugs may increase the secretion; and,
3. Give the experimental methods of determining the points where a drug acts to increase the secretion of urine.

### I. The Various Points in Mechanism.

The conceivable points in the mechanism where drugs may act to increase the secretion of urine, as seen in Diagram 5, are,—

1. The four centres in the medulla oblongata.
2. The solar or renal plexus.
3. The ends of the various nerves in the kidney.
4. The muscle of the vessel wall.
5. The renal glandular cells. Or, putting this more in detail, remember that,—
  1. Stimulation of the vaso-constrictor centre will contract renal vessels and diminish secretion.
  2. Depression of the vaso-constrictor centre will dilate renal vessels and increase secretion.
  3. Stimulation of the vaso-dilator centre will dilate renal vessels and increase secretion.
  4. Depression of the vaso-dilator centre will contract vessels and diminish secretion.
  5. Stimulation of the secretory centre will increase glandular activity and the secretion.
  6. Depression of the secretory centre will diminish glandular activity and the secretion.
  7. Stimulation of the inhibitory secretory centre will diminish glandular activity and secretion.
  8. Depression of the inhibitory secretory centre will increase glandular activity and secretion.

The same eight propositions can be formulated for the ends of the nerves as for the centres.

9. Direct stimulation of the arteriole wall in the renal vessels will contract the arteries and lessen secretion.
10. Direct depression of the arteriole wall in the renal vessels will dilate the arteries and increase secretion.
11. Direct stimulation of the glandular cells will increase secretion.
12. Direct depression of the glandular cells will lessen secretion.

### II. Possible Ways in which Drugs may act.

There are just three ways by which the secretion of urine may be increased:

1. By increasing the renal blood-pressure and circulation.
2. By increasing glandular activity in other ways than through blood-supply.
3. By lessening reabsorption from the constricted loops.

#### Action on Circulation.

I will speak of the glomerular circulation first, and then afterwards of that of the convo-

luted tubules. Because the glomeruli are specially constructed for the secretion of water, and the convoluted tubules for the secretion of retrograde products, the *circulatory apparatus* in the glomerulus is the higher developed, while the *secretory cells* in the convoluted tubule are the higher developed. Hence drugs, by acting on the circulation of the glomerulus, will affect its secretion far more than drugs acting on the circulation of the convoluted tubules will affect its secretion. For this reason much more must be said about the action of drugs on the circulation of the glomerulus than upon the circulation of the convoluted tubule.

The glomerular circulation and blood-pressure may be increased, as shown in Diagram 6, in three ways: (a) by dilating the afferent vessels, (b) by contracting the efferent vessels, and (c) by raising the general blood-pressure.

It is conceivable that the afferent vessels may be dilated,—

1. By stimulating the vaso-dilator apparatus.
2. By depressing the vaso-constrictor apparatus.

This action may be in the medulla oblongata, or solar or renal plexus, or on the ends of the nerves distributed to these vessels. In one or more of these ways the nitrites and alcohol (see Diagram 7) dilate the afferent vessels and increase the secretion of urine.

It is also conceivable that the efferent vessels may be contracted,—

1. By depressing the vaso-dilator apparatus.
2. By stimulating the vaso-constrictor apparatus.

This action also may be in the medulla oblongata, solar or renal plexus, or on the ends

of the nerves distributed to the efferent vessels. Numerous experiments appear to show that digitalis, squill, sparteine, convallaria, strychnine, and erythrophleum stimulate the vaso-constrictor centre in the medulla, causing the efferent vessels to contract, raising the blood-pressure 'in glomeruli, and increasing secretion of urine. This is seen in Diagram 7. Sehwald says that digitalis and strychnine also stimulate the ends of the vaso-constrictors. Broom, buchu, uva ursi, juniper, turpentine, copaiba, and cantharides are said to contract the efferent vessels, probably by stimulating the ends of the vaso-constrictor nerves in the vessel wall, and in that way act as diuretics. In conclusion, remember that while dilatation of the afferent vessels increases the secretion of urine, if the dilatation be excessive the secretion may be suppressed. When an excessive quantity of blood enters the capillaries of the glomerulus, the two layers of the capsule, as seen

in Diagram 7, become greatly distended and probably pressed closely together, so that there is no space for the urine to osmose into. This is what occurs in the ischuria of acute renal congestion. Again, while contracting the efferent vessels raises glomerular blood-pressure and increases secretion, yet, if it is excessive, the secretion will be lessened or even entirely suppressed, because the circulation in the glomerulus stops. This is the way, in digitalis-poisoning (see Diagram 7), the urine is suppressed.

The systemic blood-pressure may be increased,—

1. By increasing the pumping power of the heart.

2. By contracting the arterioles of the body. If at the same time the renal arterioles are contracted, this action diminishes secretion. Caffeine would be a stronger diuretic if at the same time it raises the blood-pressure it did not contract the renal arterioles. Such drugs as digitalis, strophanthus, squills, sparteine, convallaria, strychnine, and erythrophleum raise the systemic blood-pressure, which increases their action as diuretics. Those drugs that are diuretic by raising the systemic blood-pressure have, of course, far more marked action when the blood-pressure is below normal, as occurs in valvular heart-disease and debility.

3. By increasing the quantity of water in the blood-current. This is the way the secretion is increased after drinking large quantities of water. When the subcutaneous cellular tissue or serous sacs contain large amounts of water, as occurs in oedema and ascites, iodide of potassium, by causing it to re-enter the blood-current, may act as a strong diuretic, although it has no specially marked action on the kidneys. All that need be said about the circulation in the tubules is, that, as with any other gland, increasing its blood-supply increases secretion.

#### *Action on Secreting Cells.*

I will next speak of the ways in which the secreting cells may be stimulated. I will consider first the cells of the convoluted tubules, and then afterwards say something about the cubical cells of the glomeruli. It is conceivable that the secreting cells of the tubules may be stimulated,—

1. By the drug acting directly on the cells, possibly during its excretion from the body. No very elaborate experiments have been made on this subject. It may be in this way that the lithium, potassium, and sodium salts act. It is believed by some that calomel and other salts of mercury act in this way, and in proof of this they refer to the irritation, the cloudy swelling, of these cells in poisoning with mercury. They think that it increases renal activity just as it is supposed to stimulate the flow of saliva,—that is, during its elimination by the salivary and buccal glands. It might be remarked that Noel-Paton suggests that calomel acts as a diuretic by increasing the formation of urea in the liver, and that the urea acts as the diuretic. Lactose and glucose are believed to increase the secretion by acting directly on the secreting cells.

2. By stimulating the ends of the secretory nerves distributed to the cells. It may be that this is the way urea, diuretin, and one action

of caffeine excite secretion. However, some think they act directly on the cells.

3. By stimulating the secreting centre, or else the solar or renal plexus. If the recent researches of Cohnstein are correct, this is the way mercury, silver, and platinum act.

I will now say something about the action of drugs upon the cubical epithelium of the inner layer of the capsule of the glomerulus. What can

regulating the amount of water in the blood. Mammals and birds living in the air, and being subject to irregular removal of water by the skin and bowels and lack of regular supply to drink, need such a mechanism to regulate the removal of water in the urine. Hence mammals and birds have these long, constricted loops for that purpose, as shown in Diagram 8. But the fish which live in the water, and are

be said here is almost speculative, yet the physical chemical researches of Hoppe-Seyler on the osmotic relations of blood and urine, and the recent experimental research on rabbits and cats by Dreser in the Institute of Physiological Chemistry at Tübingen, throw new light upon the function of the cubical epithelium of the glomerulus and the action of drugs upon it. His experiments make it very probable that the cubical epithelium is an osmotic membrane. Increased blood-pressure in the glomerulus increases the outflow of water, not because it is a filtration, but because the pressure increases the capillary surface for the outward passage of the water, and especially because it *increases the circulation, and hence the blood is more rapidly changed* in the capillaries, so that the osmosis in this way is increased. Dreser concludes from his experiments that it is possible for drugs to act upon this osmotic membrane,—that is, the cubical epithelium,—and in that way increase the exosmosis from the blood. He thinks that caffeine and diuretin act this way. Of course, the effect would be the same whether they acted directly on the cells or on the ends of the secretory nerves distributed to them. But it must not be forgotten that no nerves have as yet been found inside the glomerulus.

#### *Action on Constricted Loops.*

The comparative anatomical researches of Hufner show that the constricted loops (Henle's loops) have the important function of causing the reabsorption of the water, as a means of

not subject to excessive loss of water, do not require any such regulating mechanism, and, as seen in diagram, they have no constricted loops. Dreser, from his experiments on rabbits, thinks that the first action in calomel diuresis is due to the mercury paralyzing these loops, so that reabsorption is lessened. He does not explain how it is supposed to act. He thinks that diuretics may yet be discovered that will not affect the glomeruli, but will act entirely by paralyzing these loops. The reabsorption of the water might be lessened by acting on the epithelium, so that it could not so easily or rapidly osmose back into the blood, or by dilating the constrictions so that the water could pass on more rapidly before there was time for its reabsorption. These might be dilated by relaxation of the unstriated muscles which, Kosturin has pointed out, surround these tubes.

No experiments whatever have been made to determine if drugs can act in this way as diuretics.

Again let me repeat that part that I have said may not be true, but it will serve its purpose if it suggests to you the importance of such knowledge,—the clinical value of knowing where a diuretic acts, and the possible lines for future research on the mode of action of diuretics.

#### *III. Methods of Experimental Research on the Actions of Drugs as Diuretics.*

I will next speak of the methods used for determining the points where a drug may act to

increase urinary secretion. It must be kept in mind that a drug may have more than one action, that it may act at more than one point in the renal mechanism, also that these actions may synergize,—that is, act together to increase diuresis,—or they may antagonize, one increasing while the other is diminishing the secretion. As an example of synergistic action may be mentioned alcohol, which raises the arterial pressure and also dilates the afferent vessels. Of antagonistic actions may be mentioned caffeine, which stimulates the convoluted tubules and increases secretion, but at the same time contracts the afferent vessels and proportionately lessens the secretion. In presenting these methods of research, since the subject is so complicated, I will, for simplicity, assume that the drugs have only one action upon the kidney.

The simplest and most common method used by experimenters is to find out, first, whether the drug acts by raising the arterial pressure. To do this all that is necessary is to introduce a manometer into the carotid artery, and record the blood-pressure before and after giving the drug. If the pressure is raised, it is concluded that the diuresis is probably due to increased blood-pressure; if it remains unchanged, then it probably acts on the secreting cells. This was the method used by Cohnstein in experimenting with diuretin on rabbits and cats. In diuretic doses the pulse and blood-pressure were unchanged; hence he thought it possible that the drug acted upon the secreting structures. But, as a means of giving you a general idea, rather than as a guide to experimental work, I will present this in a systematic manner. The order presented here will not always be practical to follow, but it will at least serve somewhat to give you an idea of how the actions of diuretics are learned. The experimenter may begin his work in several different ways. He may first decide whether the drug acts *inside* or *outside* of the kidney, or instead he may think it more convenient to determine first whether the drug acts on the *circulation* or on the *secreting cells*. I will very briefly outline both methods of procedure.

#### *First Order of Procedure.*

1. If the drug is a diuretic,—

- (1) It acts on some structure within the kidney, or
- (2) It acts on some structure outside of the kidney.

In which of these ways it acts is determined as follows:

*Demonstration.—First Method.*—As shown in Diagram 9, completely paralyze the centres

in the medulla with some drug like chloral; then, of course, drugs cannot stimulate this centre to produce diuresis. Then secure canulas in the ureters to collect urine for measuring. Measure urine for a certain number of minutes, then give the diuretic; if the secretion is increased now, when the centres in the medulla are paralyzed, the drug acts on some structure in the kidney. It is usually best to inject the drug into a vein, as it acts much quicker. But do not lose sight of the fact that the drug may have more than one action, and the other may be in the medulla oblongata. Schröder and Lanngaard used this method to show that caffeine acted on some structure in the kidney.

If the drug does not increase the secretion when these centres are paralyzed, then it is because it does not act in the kidney, but its diuretic action is due to stimulation of the medulla oblongata. This is one of the ways Cohnstein used to determine the action of mercury, silver, and platinum. He says in the chloralized rabbit these drugs will not excite secretion; therefore he concludes that they act in the medulla oblongata. His experiments need confirmation.

*Second Method.*—As shown in Diagram 9, cut one renal nerve, then the corresponding kidney will be shut off from outside influence. Secure a canula in each ureter to measure the urine from each kidney. Measure rate of secretion from each kidney, and then give the diuretic. If the drug stimulates the isolated kidney, it is by acting in the kidney; if it does not, it is because its action as a diuretic is outside of the kidney. In this way Schröder and Lanngaard showed that caffeine acted within the kidney. Cohnstein also used this method to show that mercury, silver, and platinum do not act in the kidney. Other experimenters do not agree with him. If the drug increases secretion from both kidneys, but in a greater quantity from the intact kidney, it shows that the action is both within and without the kidney.

**Third Method.**—As shown in Diagram 9, the kidney is excised and placed in an apparatus (not shown or described here) specially constructed to keep up proper pressure, temperature, and artificial circulation of blood-and-salt solution through canula in renal artery. Munk devised this apparatus some years ago. Recently Jacoby and Sobieranski, in the Pharmacological Institute in Marburg, have constructed an instrument for carrying on artificial circulation in the kidney, which they call a *hamatisator*. After the kidney is placed in the apparatus and the circulation started, the rate of secretion of urine is next to be measured by taking it from canula in ureter; then add the drug to the liquid which is to pass through the kidney. If the secretion is increased, it shows that the drug acts in the kidney; if it is not increased, then it acts without the kidney. In this way it has been shown that chloride of sodium, nitrate of sodium, nitrate of potassium, caffeine, dextrose, cane-sugar, and glycerin stimulate secretion by acting within the kidney. Having now learned how to determine whether the action is in or outside the kidney, you will next study each of these.

2. If the drug acts inside the kidney to increase the secretion,—

- (1) It dilates the renal arterioles; or
- (2) It contracts the efferent vessels; or
- (3) It stimulates the secreting cells.

The next thing to do is to determine in which of these ways it acts.

**Demonstration.**—Secure canula in one renal vein, as seen in Diagram 10, and measure rate of outflow from vein before and after giving the diuretic. If the venous flow is increased by the drug, the secretion is due (a) to dilatation of the renal arterioles; if it is diminished, the secretion is due (b) to contraction of the efferent vessels; and if it remains unchanged, the secretion is due (c) to action upon the secreting cells.

3. If the drug acts outside of the kidney to increase the secretion,—

- (1) It raises the general blood-pressure; or
- (2) It dilates the renal arterioles by acting in the medulla oblongata; or
- (3) It contracts the efferent vessels of the glomeruli by acting in the medulla; or
- (4) It stimulates the secretory cells by acting in the medulla oblongata.

The next thing is to determine in which of these four ways it acts.

**Demonstration.**—Introduce manometer in the carotid artery and canula in the ureter. Record blood-pressure before and after giving the diuretic. If the pressure is raised, then the drug

acts as a diuretic, at least in this way. If the systemic blood-pressure remains unchanged, then the diuresis is produced in one of the other ways. Cohnstein used this method to

determine whether calomel increased secretion by raising blood-pressure or by acting on one of the centres in the medulla oblongata. Having excluded systemic blood-pressure, you will next determine which of the centres in the medulla oblongata it acts upon. This action on the medulla causes either the afferent vessels to dilate, the efferent to contract, or the secreting cells to become more active.

**Demonstration.**—Which of these three it acts upon is determined as previously described.

#### *Second Order of Procedure.*

1. If the drug is a diuretic,—

- (1) It acts on the circulatory mechanism; or
- (2) It acts on the secretory mechanism.

The next thing is to determine on which of these two mechanisms the drug acts.

**Demonstration.**—Secure canula in one of the renal veins, and measure rate of flow before and after giving the drug. The outflow of blood can be measured by counting the drops, or, more accurately, by the graphic method,—that is, by an electric marker that will record each drop. If the venous outflow remains unchanged, the action is on secretory mechanism; but if it is increased or diminished, the action is on circulatory mechanism. Having now learned how to determine on which of the two mechanisms it acts, you will next consider each separately.

2. If the drug is a diuretic, because it stimulates the secretory mechanism,—

(1) It acts upon the centre in the medulla; or

(2) It acts in the kidney on the secreting cells or ends of nerves distributed to them.

*Demonstration.*—Isolate kidney in the three ways already described and give the drug.

3. If it is a diuretic by acting upon the circulatory mechanism,—

(1) It dilates the renal arterioles; or

(2) It contracts the efferent vessels; or

(3) It raises the systemic blood-pressure.

Next determine in which of these three ways it acts.

*Demonstration.*—Measure blood-pressure, and if not changed by the diuretic, then it acts in one of the other two ways. Measure rate of flow through renal vein; if the drug increases it, the arterioles are dilated; if it decreases it, the efferent vessels are contracted.

4. If it is a diuretic by dilating the renal arterioles,—

(1) It acts in the kidney to produce this dilatation; or

(2) It acts in the medulla oblongata (probably).

Next determine this.

*Demonstration.*—This may be determined in one of three ways,—by completely paralyzing the vaso-motor centres in the medulla oblongata, or by cutting the renal nerves, or by using the excised kidney. If in either of these three experiments the drug stimulates secretion, it is by acting in the kidney.

5. If the drug is a diuretic by contracting the efferent vessels,—

(1) It acts upon them in the kidney; or

(2) It acts upon the centre in the medulla.

*Demonstration* same as the last.

6. If the drug is a diuretic by raising the systemic blood-pressure,—

(1) It increases the pumping power of the heart; or

(2) It contracts the systemic arterioles.

*Demonstration.*—Secure canula in the peripheral end of femoral vein. Observe rate of out-flow before and after the drug is given. If the flow is lessened, the arterioles are contracted; if increased, the heart is stimulated; if unchanged, or very slightly, probably both the heart and arterioles are acted upon.

#### ON REACTION OF URINE IN HEALTH.

In health the acidity of the urine is due mainly to acid phosphate of sodium, or, if there has been an excessive meat diet, to acid phosphate of potassium. The acid phosphate is

formed from the basic phosphate during its exosmosis from the blood through the renal cells. This occurs because the nature of the epithelium is such that in health the acid is drawn through more rapidly than the base, and hence the decomposition and formation of the acid phosphate, of acid urine from alkaline blood. It is a well-recognized physical fact that osmotic force can cause chemical decomposition.

The reaction of the urine can be changed in two ways,—

1. By changing the reaction of the blood; and,

2. By affecting the activity of the renal mechanism.

#### *Action on Blood.*

Before speaking of how to change the reaction of the blood and in that way the reaction of the urine, I will say something about how the reaction of the urine is affected by that of the blood. Since the urine is formed from the blood, it is natural to suppose that the more alkali in the blood the more tendency there would be for it to appear in the urine, and this is the case. Normally, the renal epithelium is capable of converting the basic into acid salt; but if there is too much, then it no longer is capable of doing this, and hence the reaction of the urine may become alkaline.

The reaction of the blood may be changed by removing or adding acids to it and by removing or adding alkalies to it.

The blood may be made more alkaline,—

1. By adding alkalies to it. Hence the hydrates and carbonates of sodium, potassium, and lithium increase its alkalinity; also the vegetable salts of these alkalies, since in the blood they become oxidized into the carbonates.

2. By removing or preventing the normal entrance of acids into the blood. During digestion there is a large quantity of hydrochloric acid secreted in the stomach, the removal of which from the blood just so much alkalizes it, because the sodium with which it was combined as a neutral salt in the blood is now acting as an alkali. The precipitation and consequent prevention of the acids in the food being absorbed and entering the blood will increase the alkalinity of the blood. This is specially true of phosphoric acid, which forms insoluble salts with calcium and magnesium; hence if at meal-time lime or magnesia be given, it will precipitate and prevent the phosphoric acid of the food entering the blood, and of course will increase the alkalinity of the blood. Vegetable food increases the alkalinity of the blood in both these ways. It contains more sodium and potassium than animal food, and hence adds

more alkalies to the blood; it also contains more lime and magnesia, hence prevents the phosphoric acid entering the blood. This is the reason carnivora have acid and herbivora alkaline urine.

The blood may be made less alkaline,—

1. By adding acids to it. This occurs when large quantities of the mineral acids, except nitric, well diluted with water, are given; also, to a less extent, when the vegetable acids are taken. Salicylic, and especially benzoic, acids are about the only ones used for this purpose. There is nothing known about lessening the alkalinity of the blood by removing the alkalies from it, or by precipitating them in the digestive tract so that they will not enter the blood. But the alkalinity can be lessened by using a meat diet, which contains less alkalies.

#### *Action on Renal Mechanism.*

Just as it has been known for years that adding an alkali or acid to a solution changes its reaction, so it has been known that giving acids or alkalies will affect the reaction of the urine; but it is only recently that it has been learned that the reaction can be changed in an entirely different way,—that is, without any regard to the chemical law just mentioned. This action is not dependent on whether the drug is acid, alkaline, or neutral. When the diuresis is increased, when a large quantity of water is excreted, the urine becomes less acid, or may even become alkaline. The greater the quantity of water excreted the more nearly the reaction approaches that of the blood; hence drugs that increase glomerular activity lessen the acidity of the urine. It would seem that the basic phosphate, when it exosmoses with a large quantity of water, is not so easily decomposed into the acid phosphate as occurs in the normal secretion. Riedel, in the Pharmacological Institute in Heidelberg, experimented with rabbits and dogs as to the influence of diuresis on the reaction of the urine. In order to exclude the influence of digestion he withheld food from them for several hours before the experiments. He withheld the food from the rabbits nineteen hours or more, so that the urine would become acid before he began the experiment. He found that neutral salts, like sodium chloride, sodium sulphate, sodium nitrate, also theobromine and sugar, caused the acid urine to become neutral, then later alkaline, and again acid, as the effect of the drug wore away.

#### ON COMPOSITION OF THE URINE.

*I. Drugs contracting the Efferent Vessels.*—This action causes the following to occur:

1. Less blood passes through the kidney.
2. Hence less urea is excreted.
3. More water is excreted by the glomeruli because the glomerular pressure is raised. Therefore these drugs diminish urea and increase the water.

*II. Drugs dilating the Afferent Vessels.*—This action causes the following to occur:

1. More blood passes through the kidney.
2. Hence more urea is excreted.
3. More water is excreted by the glomeruli because the glomerular pressure and circulation is increased. Therefore these drugs greatly increase the water and slightly the urea.

*III. Drugs stimulating the Convoluted Tubules.*—This action causes the following to occur:

1. Same amount of blood passes through the kidneys.
2. Far more urea and slightly more water by the convoluted tubules.
3. The same amount of water is excreted by the glomeruli. Therefore these drugs slightly increase the water and greatly increase the urea.

*IV. Drugs paralysing the Constricted Loops.*—Nothing is known about this, but if a drug should be found to act solely in this way, it is probable that the following would occur:

1. Same amount of blood would pass through the kidneys.
2. Same amount of urea would be excreted.
3. Same amount of water would be excreted.
4. Little water would be reabsorbed. Therefore such a drug would increase the water, while the urea would remain the same.

#### ACTION OF DIURETICS IN DISEASE.

On first thought it might be supposed that diuretics would be used mainly in the treatment of disease of the kidneys, but they are rarely used for this purpose. When in nephritis the function of the kidneys is compromised, causing symptoms from the accumulation of waste in the body, diuretics given to stimulate the diseased kidneys, as a rule, will increase the trouble. It is usually best to try to make the skin and intestines do the work of the crippled kidneys for the time being. Sometimes, though, the alkaline diuretics may be of service, because, instead of determining blood to the kidneys, they may simply deplete the kidneys by increasing outward osmosis through the secreting cells, and in that way remove the waste from the blood without doing the kidneys any harm. But if there is extensive injury of the renal structure, you cannot expect any diuretic

to increase the secretion. There are, however, pathological conditions in other organs where diuretics may often be of great service. These conditions are different, sometimes directly opposite; hence to be of service in a certain condition it is not sufficient that the drug simply increase the flow of urine, but it must do this in a certain way. So you see the advantage of knowing the exact points in the mechanism where the drug acts in order to select the proper diuretic upon a rational basis. Aside from their limited use in the treatment of disease of the kidneys, diuretics are indicated in the treatment of the six following pathological conditions:

1. *To remove Excessive Accumulations of Water in the Body when the Blood-Pressure is too Low.*—In cardiac insufficiency there is low arterial and high venous pressure, and, as a consequence, there is not only dropsy, but lessening of the urine because of the low blood-pressure. The diuretics to select here to increase the urine are those that raise the blood-pressure by increasing the pumping power of the heart. These drugs are of great service, because this action on the heart not only increases the urine and removes the dropsical effusion, but at the same time prevents the further accumulation of effusion. Digitalis, strophanthus, and squill render prompt service in this condition. A diuretic which acted only on the kidney without being combined with one which increased the action of the heart would not be of much service, and one which lowered the blood-pressure would do great harm. Sometimes it may be advantageous to combine other diuretics with such drugs as digitalis to hasten the removal of the water from the tissues. Greater secretion will result if diuretics acting at different points are used together:

- (1) Digitalis to raise systemic blood-pressure.
- (2) Broom to contract the efferent vessels of the kidney.
- (3) Sweet spirit of nitre to dilate the afferent vessels of the kidney.
- (4) Acetate of potassium to stimulate the convoluted tubules.

2. *To remove Excessive Accumulations of Water in the Tissues which is not Due to Low Arterial Pressure.*—In this condition diuretics are of nothing like the service they are in heart-disease. In hepatic cirrhosis the passage of the portal blood through the liver is obstructed, and, as a result, there is leakage from the distended portal vessels into the peritoneal cavity. If diuretics are used to remove this, it is not so important that they raise the arterial

pressure, as is the case in heart-disease. A diuretic is wanted that causes a large quantity of water to be secreted regardless of its effect upon the blood-pressure.

But hydragogue cathartics are far more efficient than diuretics, because they lower the abnormally high portal pressure and stop the outward passage of the water into the peritoneal cavity.

3. *To remove Water from the Blood when the Arterial Pressure is too High.*—At the onset of many acute diseases, as tonsillitis, bronchitis, etc., there is high arterial tension, which hastens the extension of the disease. This high pressure may be lowered by diuretics, which, by draining a large quantity of water from the blood, lower the pressure. It is evident that such diuretics as raise the arterial pressure will do harm by still further increasing the high pressure. For this purpose it is best to select a diuretic—

(1) That will greatly increase the secretion of water, either by dilating the afferent or contracting the efferent vessels of the kidney.

(2) That will lower the systemic blood-pressure.

(3) That will at the same time produce marked diaphoresis.

Because sweet spirit of nitre dilates the systemic arterioles, causes diaphoresis, and increases the secretion of urine by dilating the afferent vessels of the kidney, it is often used with benefit during the first hours of acute sthenic fevers.

4. *To remove Waste from the Body.*—Sometimes in disease there is excessive production of waste. This occurs in rheumatism, gout, uric-acid diathesis, and in many acute diseases. For this purpose those diuretics which stimulate the convoluted tubules and increase the secretion of waste products are indicated. They are of still more service if at the same time while circulating in the blood they increase oxidation and burn up this pathological material; hence the alkalies—lithium and potassium—are of service here because they increase oxidation as well as hasten the removal of waste by the kidneys.

5. *To lessen the Acidity of the Urine.*—In debility and other conditions sometimes the urine is excessively acid, and, as a result, there is frequent micturition from the irritation. In the uric-acid diathesis there may be irritation from the uric-acid crystals. Or, again, the urine may not be too acid, but the urinary tract may be inflamed, as occurs in gonorrhoea, so that the normal urine causes irritation. For all these cases the alkaline diuretics are of service.

6. *To increase the Acidity of the Urine.*—In cystitis and other affections there is sometimes ammoniacal decomposition of urine, which, by its irritation, causes frequent painful micturition. For this purpose benzoic acid, salol, and other salts of salicylic acid are used.

#### THE ADVANTAGES OF AMORPHOUS PHOSPHORUS OVER THE OFFICIAL FORM.

BY E. Q. THORNTON, M.D.,

Demonstrator of Therapeutics, Jefferson Medical College.

THE investigations of Wegner, Bradley, Broadbent, Thompson, and others should leave little doubt as to the value of phosphorus as a stimulant to bone-growth and in the treatment of disorders due to exhaustion or wasting of the nervous tissues. The remedy, while undoubtedly possessing power potent for good, has the great disadvantage of not being entirely safe, as disorders of digestion, nephritis, and fatty degeneration are not infrequently attributed to its administration. On account of these untoward effects many authors have wisely insisted upon the utmost precaution in its use. As is well known, the form of phosphorus exclusively employed in medicine is the vitreous variety, from which both of the official preparations are made. Both of these preparations are open to the objections named above, and on account of the readiness of phosphorus to undergo change when exposed to the air, the pills are necessarily made by a complicated process which renders their extemporaneous manufacture difficult. As to phosphorated oil, the other official preparation, its taste is ex-

treinely nauseous, as may be inferred from its combination (phosphorus, ether, and oil).

It is on account of these disadvantages of the vitreous phosphorus that I am led to suggest the employment of the amorphous or red variety. The amorphous phosphorus is made by heating the vitreous variety to 250° C. in the absence of air, and possesses the following advantages over the official variety: It does not readily undergo change at ordinary temperatures; it is almost entirely without taste or odor, therefore it can readily be made into pills at a moment's notice; it is free from irritant or caustic effect, consequently it is far less liable to give rise to irritation or inflammation of the gastro-intestinal and genito-urinary tract; but its greatest advantage lies in the fact that it is non-toxic and therefore far safer.

That it has the same physiological effect as ordinary phosphorus seems to be proved beyond doubt by Kelly, who, while experimenting upon himself to determine if it was toxic, experienced the full physiological effects of vitreous phosphorus. The following brief extracts are made from Kelly's essay, which has never been published:

*Experiment 1.*—For the first three days  $\frac{1}{10}$  grain of amorphous phosphorus was taken every two hours, nine doses being taken each day. On the fourth day each dose was increased to  $\frac{3}{10}$  grain, and from the tenth until the twenty-fifth day  $\frac{1}{10}$  grain every two hours, nine doses a day being taken.

*Effect.*—Mental excitement, headache, vertigo, priapism, nocturnal emissions of semen, followed about the twentieth day by nervous exhaustion.

Return to his normal healthy condition in about two weeks after discontinuing the drug.

*Experiment 2.*—About two weeks after completing Experiment 1 he again began taking amorphous phosphorus in doses of  $\frac{1}{10}$  grain, increased on the fifth day to  $\frac{2}{10}$ , and on the tenth day to  $\frac{4}{10}$  grain, nine doses being taken each day.

Priapism and nocturnal seminal emissions were among the most pronounced effects. The drug was discontinued on the seventeenth day, and he soon returned to his normal condition.

*Experiment 3.*—About six weeks after completing Experiment 2 he took at a single dose 20 grains of amorphous phosphorus. The physiological effects came on promptly. Priapism, vertigo, nausea, followed by muscular tremors, cold, clammy skin, great exhaustion, and the most pronounced effects. For some weeks he was in a state of nervous exhaustion, from which he gradually returned to his normal

condition. He is now in good health and shows no ill effect of this rather vigorous medication.

Beese publishes a case in which 30 grains of amorphous phosphorus were taken by a young woman with suicidal intent, no toxic symptoms having been manifested.

My own experiments upon animals are in accord with those who assert that the substance in large quantities is non-toxic. My investigations as to the effect of long-continued doses is as yet incomplete.

These records would seem to indicate that amorphous phosphorus, while having the same physiological action as the vitreous variety, is to be preferred, as it is much easier to administer, less irritating, and, above all, is a far safer remedy.

*THE USE OF SUBCONJUNCTIVAL INJECTIONS OF MERCURIC BICHLORIDE IN VARIOUS OCULAR AFFECTIONS, WITH A REPORT OF FIFTEEN CASES SO TREATED.*

READ BEFORE THE PHILADELPHIA COUNTY MEDICAL SOCIETY,  
DECEMBER 27, 1893.

BY C. A. VEASEY, M.D.,

Clinical Assistant to the Ophthalmological Department of the Jefferson Medical College Hospital; Consulting Ophthalmic Surgeon to the Philadelphia Lying-in Charity and Nurse Training-School.

**D**URING the past two or three years much has been written concerning the subconjunctival injections of antiseptic solutions in various affections of the eye, especially by French surgeons, who are the strongest advocates of the method.

It is by no means a new procedure, for, as early as 1866, Rothmund\* used a solution of sodium chloride in this manner for clearing up corneal opacities; and since this time, but more especially within the past four or five years, various surgeons have employed the method in the treatment of numerous ocular diseases.

Valude, the editor of the *Annales d'Oculistique*, in the early part of this year sent a communication to many oculists in different parts of the world, asking a number of questions in regard to the method, in order that proper conclusions could be formed by comparing the experiences of many. The results of this inquiry have been recently published,† and the experience of the large majority of the French surgeons included therein is in favor of the method.

It is not the purpose of the present paper to discuss the theory of subconjunctival injections and the value of the different drugs that have been employed in making them. Those interested are referred to the articles by Darier, which were published in the *Archives d'Ophthalmologie*, 1891, p. 449, and in the *Annales d'Oculistique*, April, 1893; also to the clinical lecture of Dr. de Schweinitz in the THERAPEUTIC GAZETTE, June, 1893.

The manner of making the injections is as follows: The conjunctival cul-de-sac is thoroughly cleansed with a freshly-made saturated solution of boric acid or with a solution of bichloride of mercury (1 to 8000), a few drops of a four-per-cent. solution of cocaine are instilled, and as soon as anæsthesia is produced the lids are separated by an assistant, while with a pair of fixation forceps the conjunctiva is seized about eight millimetres from the corneal margin, lifted up, and, the needle of the syringe having been inserted, the desired amount is forced out. The injection is made by Darier with a Pravaz syringe, but an ordinary hypodermic syringe, with a platinum needle, will answer the purpose very well. It is of the utmost importance, to be sure, that the barrel of the syringe be made thoroughly aseptic by the use of a strong solution of sublimate or carbolic acid; the needle should be brought to a red heat in the flame of an alcohol lamp prior to each injection, for a similar purpose. In fact, all the precautions against infection are taken just as if a corneal section were to be made.

If this be done, the danger of serious complications is reduced to a minimum. Slight chemosis follows each injection, but soon passes away. Occasionally a small conjunctival blood-vessel is punctured, giving rise to a considerable hemorrhage, but, beyond the discoloration thus produced, the accident is of little consequence. The cases of keratitis, or hypopyon keratitis, that have been reported as following an injection must have been due more to the imperfect sterilization of the instruments than to the operation itself. I have never seen such a complication.

The frequency of the injections, as well as the dose, depends upon the severity of the case. The strength of the solution employed is 1 to 1000, and the amount of the first injection about two minims. Much more than two minims has been given at a single injection, and repeated daily. But it seems to be generally conceded that it is better to begin with small doses, frequently repeated, say every other day, and to increase gradually the quantity in-

\* *Klinische Monatsblätter für Augenheilkunde*, 1866, p. 171.

† *Annales d'Oculistique*, August, 1893, p. 145.

jected as the idiosyncrasies of the patient are ascertained and the severity of the affection demands.

As to the number of injections to be made before the treatment should be abandoned, in case no improvement is observed after the first two or three have been given, no fixed rule can be followed. Darier says it is useless to continue after ten injections have been made if some improvement has not been noticed. On the contrary, as many as fifty or sixty have been given in a single case, with improvement. But, generally, if any benefit will accrue from the use of this method, it will be noticeable after a few injections, and the length of time the treatment should be continued depends upon the progress of the case, each being a law unto itself.

The cases in which the method has been employed by various observers are widely different, but all surgeons seem to agree that it should not be used when there is present any vascular stasis sufficient to prevent the quick absorption of the remedy. The replies to Valude's letter of inquiry indicate that the best results are obtained in diseases of the uveal tract, chronic in nature, though there are also reports of excellent results having been obtained in diseases affecting other portions of the eye.

The following cases, reported by request of Dr. de Schweinitz, represent the diseases which have received the treatment in his service in the Jefferson Medical College Hospital:

CASE I.—*Scleritis*.—B. S., female, aged forty-three, housekeeper, presented herself at the eye dispensary with a well-marked scleritis in the left eye. There were two large patches of infiltration, one above and one to the outer side of the cornea. The ciliary pain was intense and the cornea somewhat thickened. No history of syphilis or rheumatism. The vision of the right eye equalled  $\frac{2}{80}$ ; of the left,  $\frac{1}{80}$ . After using both local and constitutional treatment for some time without any benefit, we had recourse to the subconjunctival injections of sublimate.

On the 28th of April  $1\frac{1}{2}$  minims were injected just above the cornea and near the patch of infiltration. On May 1, three days later, the pain had entirely disappeared, the bulbar injection was almost gone, and the two patches of infiltration were much smaller. On this day an injection was made below the cornea. The patient did not return until May 12, saying she had felt so well she had thought it unnecessary to come earlier. There still being a little bulbar inflammation, however, a third injection was given, this time amounting to 2 minims.

On May 20 the patient was to all appearances rid of the attack, and was dismissed from further attendance. Her vision on this date was for O. D.,  $\frac{2}{80}$ ; for O. S.,  $\frac{2}{80}$ .

CASE II.—*Syphilitic Serous Iritis (Keratitis Punctata)*.—F. M., male, aged nineteen, morocco-worker; had an attack of gonorrhoea nine months before he presented himself for ocular treatment, followed a month later by a hard chancre. The ocular disease dates from this time. Treatment had been received during his first attack for three and a half months at another hospital. In each eye there were found traces of old iritic inflammation, and the corneas were infiltrated and hazy. Vision for O. D. equalled  $\frac{2}{80}$ ; for O. S.,  $\frac{1}{80}$ . On April 28 he was given an injection of sublimate beneath the conjunctiva, and between this time and August 14 he received fourteen injections. The vision on this date was for O. D.,  $\frac{2}{80}$ ; for O. S.,  $\frac{2}{80}$ ; a very great improvement.

CASE III.—*Syphilitic Irido-Cyclitis*.—J. M., male, aged twenty-nine, driver, with well-marked irido-cyclitis in the right eye, of syphilitic origin, with a contracted pupil, pericorneal injection, intense pain, and numerous posterior synechiæ, presented himself for treatment on April 10. The usual treatment was given, including leeches to the temple; but on the 20th he did not seem to be any better. We then gave him an injection of sublimate, and on the 28th he was so much improved that another was given. On May 1, three days later, the ciliary inflammation was gone, the pupil round, and the vision, which before the treatment was for O. D.  $\frac{2}{80}$  and for O. S.  $\frac{2}{80}$ , was now  $\frac{2}{80}$  for each eye.

CASE IV.—*Corneal Ulcers*.—M. E., male, aged thirteen, tobacco-stripper, came on March 23 to obtain treatment for recurring phlyctenular ulcers of the left eye. There was one large infiltrated ulcer in the lower inner quadrant of the cornea, with several smaller ones surrounding it. Large maculæ existed as sequelæ of former ulceration. He received the customary treatment, and the ulcers healed very sluggishly.

Having presented himself with a third attack, he was given three injections of sublimate at proper intervals, the injections being made in that portion of the conjunctiva nearest the ulcers. They healed about as quickly as with the ordinary treatment, the disturbance after each injection being such that considerable time had to elapse before another could be given. After the treatment his vision was the same as when he was first seen.

CASE V.—*Syphilitic Plastic Iritis*.—M. J.,

male, aged thirty-five, coachman. Iritis in right eye of one week's duration. Intense ciliary injection, extreme tenderness, pupil small and immobile. There had been a papular eruption on his body some months before. His vision was for O. D.,  $\frac{7}{8}$ ; for O. S.,  $\frac{3}{8}$ . One injection of sublimate was given, and on the following day the tenderness had disappeared, the ciliary injection was very much diminished, and the pupil was large and round. After this the patient was not again seen; so whether he continued to improve so rapidly that he thought it unnecessary to come to the dispensary again, or whether he became worse and applied elsewhere for treatment is only a matter of conjecture.

CASE VI.—*Syphilitic Plastic Iritis*.—A. P., female, aged fifty-two, housekeeper. Iritis in right eye of three weeks' duration. Vision for O. D.,  $\frac{2}{10}$ ; for O. S.,  $\frac{3}{8}$ . Pupil small and slightly oval horizontally, but immobile. Initial lesion ten years ago. Same eye inflamed twice before. Patient was given two injections of sublimate, after which the inflammatory symptoms had subsided, but there remained a slight attachment of the iris below. One month later a similar inflammation developed in the left eye, but one injection completely dissipated it, leaving no synechia.

CASE VII.—*Non-specific Parenchymatous Keratitis*.—J. B., male, aged twenty-eight, machinist, presented himself for treatment with a well-developed inflammation in the left eye, characterized by diffuse infiltration in the parenchyma of the cornea. The vision of this eye has always been poor, but a change for the worse was noticed four weeks ago. Denies any specific history. After a fair trial of internal and local medication, with very little improvement, he was given, at proper intervals, sixteen injections of sublimate. At the time the treatment was commenced his vision was for O. D.,  $\frac{2}{8}$ , partial, and for O. S.,  $\frac{7}{8}$ . At the time of the last injection it was for O. D.,  $\frac{4}{8}$  and for O. S.,  $\frac{3}{8}$ . The cornea of the left eye was comparatively clear. He had compound hypermetropic astigmatism, but the proper correction failed to make him see any lower on the test-card.

CASE VIII.—*Syphilitic Plastic Iritis*.—M. S., male, aged thirty, laborer. Iritis in right eye. Has had previous attacks. Patient is illiterate and a Russian, so it is impossible to obtain vision. One injection of sublimate reduced the inflammatory symptoms, leaving the pupil round and mobile.

CASE IX.—*Syphilitic Serous Iritis*.—A. G., male, aged twenty-eight, laborer. Well-marked specific iritis, serous in type, in the right eye.

There have been a number of previous attacks. Vision for O. D. is  $\frac{3}{8}$  and for O. S.,  $\frac{3}{8}$ . One injection was given, and two days later, when patient returned, the inflammation had subsided, the pupil was round, and the vision for each eye was  $\frac{3}{8}$ . Three months later this patient had another attack in the same eye, which was promptly checked by two injections.

CASE X.—*Interstitial Keratitis*.—F. A., male, aged twelve, presented himself with a most severe interstitial keratitis, of a scrofulous type, in both eyes. The lachrymation and photophobia were so great that it was impossible to measure his acuity of vision. He was given four injections of sublimate at differing intervals, his conjunctivitis being treated at the same time. At the expiration of this time—about two weeks—the patient left the hospital, but was much improved, readily counting fingers at twelve inches, both eyes being open and free from irritation, although no change in the corneal infiltration had occurred.

CASE XI.—*Interstitial Keratitis*.—P. L., female, aged seven. Has had badly-inflamed eyes since eight months of age, at which time there was present otitis media purulenta and a skin eruption covering almost the entire body. That peculiar variety of teeth to which Hutchinson's name has become attached is also present. The disease has been marked with frequent improvements and exacerbations. At the time the patient was first seen, the opaqueness of the cornea was so great that the pupils could scarcely be distinguished. Vision equalled the counting of fingers at six inches. In addition to the corneal inflammation there was a severe mucopurulent conjunctivitis and a chronic rhinitis. After the nasal and conjunctival inflammations had been somewhat reduced and internal medication had been employed, the vision became  $\frac{3}{8}$  for each eye. Subconjunctival injections of bichloride were now tried at three different times, but the eyes became so much worse after each trial, the vision being reduced to  $\frac{2}{10}$  for each eye, that this form of treatment had to be abandoned. Internal medication combined with local measures are now being used, and the patient is still improving.

CASE XII.—*Syphilitic Plastic Iritis*.—F. W., male, aged twenty-six, carpenter. Traces of old iritis in both eyes; now, a fresh attack in the left eye; initial lesion six months ago. Two injections of sublimate were sufficient to reduce the inflammatory symptoms.

CASE XIII.—*Scleritis*.—M. D., female, aged twenty-eight, housekeeper, presented herself for treatment of a severe scleritis of ten days' duration. Has had two previous attacks in the

same eye, the first six years ago, the second two and a half years ago. Each time the attack lasted for several weeks. Tension is —2; patient is pregnant. After employing the usual means of treatment for three weeks, with no improvement, an injection of sublimate was given. On the following day the inflammation had subsided considerably and there was less pain. The improvement continued for four days, when another injection was given; but the reaction from the last one was so great, and the eye suddenly became so much worse, that this plan of medication was abandoned.

CASE XIV.—*Gonorrhœal Iritis*.—J. R., male, aged twenty-five. Two years ago had gonorrhœal iritis, following an arthritis of the knee and ankle of like origin, exceedingly stubborn in character, lasting for many weeks. Present attack (May 1, 1893) confined to the right eye, beginning five days before examination. Typical plastic iritis, associated with violent pain. Vision  $\frac{1}{8}$ , barely. Two injections of the sublimate solution given respectively May 1, 1893, and May 5, 1893. Twenty-four hours after the first injection, iris free and pupil round. One week after second injection, irritation entirely subsided; vision  $\frac{1}{8}$ .

CASE XV.—*Corneal Ulcer*.—J. K., male, aged sixty-one, presented himself for treatment May 15, 1893, with a large sloughing ulcer of the cornea in its lower portion and prolapse of the iris, the preserved portion of the anterior chamber being filled with blood and the bulbar conjunctiva swollen and œdematous; tension diminished; vision equals faint light perception. Atropine and boric acid ordered locally, and May 16, 1893, a subconjunctival injection of sublimate was given. Immediately afterwards intense pain and chemosis, which lasted for the rest of the day and during the night, and when he appeared the following day the eye was so swollen that the injection was not repeated. The ulcer was even more ragged and unhealthy than on the previous day. Under iodoform insufflations and a pressure bandage rapid healing took place.

To recapitulate, there were the following cases: 2 scleritis, 1 interstitial keratitis (scrofulous), 1 interstitial keratitis (specific), 1 parenchymatous keratitis (non-specific), 1 syphilitic irido-cyclitis, 2 syphilitic serous iritis, 4 syphilitic plastic iritis, 1 gonorrhœal iritis, 2 corneal ulcer.

In the two cases of scleritis the results in one were good, while in the other, after the first injection, they were negative.

In the interstitial keratitis of a scrofulous

type the patient's condition was rapidly improving, but he discontinued the treatment.

In the specific interstitial keratitis the injections created such a disturbance that they had to be abandoned.

The case of non-specific parenchymatous keratitis was rapidly improved.

In the two cases of corneal ulceration, one was relieved of the inflammatory symptoms about as rapidly as with the ordinary method of treatment, while in the other the treatment was discontinued on account of the great degree of inflammation which followed the first injection.

In all the cases of iritis and in the case of irido-cyclitis the method gave prompt and effectual relief.

A solution of atropine was employed in each case from the beginning of the treatment; but in several of the cases of iritis it was used without result for several days, and on the day following an injection of sublimate, the synechiæ, as a rule, were broken and the pupils round.

125 NORTH SEVENTEENTH STREET.

#### A CASE OF VIOLENT BLEPHAROSPASM, WITH CURE.

Merz (*Klin. Monatsbl. f. Augenheilk.*, October, 1893) reports the case of a patient with violent cramp of the orbicular muscle, clonic in type, lasting from ten to twenty seconds at a time. The lid could then be opened, but there was quick repetition of the cramp. There was slight conjunctival catarrh and incipient cataract, with normal ophthalmoscopic appearances. There was contraction of the visual field for form and colors. Soothing local applications were of little moment, and the patient was given ichthyol internally, and ordered to wear a band around the brow composed of alternating strips of leather and metal. Some improvement followed this, but the marked and rapid cure of the case resulted after the injection of strychnia into the region of the supraorbital nerve, pressure on which temporarily stayed the spasmodic movements. In concluding, the author attributes only a very slight influence to the treatment by suggestion,—namely, the administration of ichthyol and the wearing of the band around the forehead. A definite improvement occurred only after the strychnine injections, and also in a very short time, and he believes that it was due to the effect of these upon the supraorbital nerves.

### THE TREATMENT OF GALL-STONE COLIC.

THE treatment of gall-stone colic, except so far as the administration of morphine by the hypodermic needle is concerned, is to a very great extent a bugbear to the practitioner of medicine. Yet the condition is one which demands that active measures for the relief of the attack which is present and the prevention of all future attacks should be instituted. Within the last few years a large number of writers in America and Europe have spoken in high praise of the employment of olive oil in large doses for the relief of an attack when once developed. Others have spoken equally enthusiastically of turpentine, and still others have recommended phosphate of sodium or Glauber's salt, both for the relief of the attack and for the prevention of subsequent illnesses. These remedies, of course, do not make up the

entire list of drugs which have been employed in this aggravating condition, but may be considered, with perhaps the addition of potassium iodide and salicylate of sodium, as being those which have received the highest praise within recent years. In the *Manchester Medical Chronicle* for December, 1893, Dr. Brockbank has contributed a valuable and interesting article upon the pathology, etiology, and treatment of gall-stone, in which he considers the formation and composition of these stones as they occur in man and the lower animals, and calls attention to the fact that the disease is quite frequent among Anglo-Saxons, but very rare in Eastern countries. Thus, in the Royal Infirmary in Manchester an examination of the post-mortem records showed that gall-stones were found in nearly three per cent. of all the males and nearly eight per cent. of all the females on whom a post-mortem examination was made.

In order to determine what remedies could be used most rationally in this condition, Brockbank instituted a series of interesting investigations as to the solvent power of drugs upon gall-stones outside of the body, although he recognizes the fact that the conditions under these circumstances are quite different from those which exist during an attack. As a result of these studies he finds that none of the inorganic drugs have any solvent power whatever upon gall-stones, although by freeing the portal circulation and keeping the alimentary canal clear of fæces he believes that they are powerful adjuvants to treatment. He finds, on the other hand, that gall-stones placed in olive oil undergo comparatively rapid solution, so that nearly seventy per cent. of their weight is lost in the course of ten days. Still more powerful for the solution and breaking up of the stones did he find the animal soap of the British Pharmacopœia, which caused a very much more rapid solution of these bodies.

He is, therefore, inclined to believe that the olive-oil treatment of gall-stones is based on the most rational principles; but it is not to be forgotten that under natural circumstances the stone is very largely protected from the action of the oil, and that when olive oil has seemed to give relief it has fortunately acted more promptly than the time required in his experiments. Brockbank is inclined to explain this by supposing that olive oil acts as an efficient antispasmodic as well as lubricant and solvent, and that the relaxation of the spasm of the gall-ducts and of the muscular fibres in the wall of the intestine, combined with partial solution or softening of the surface of the stone, explains how olive oil, when given in full dose during

an attack of colic, frequently gives relief. He believes that in those cases where the oil cannot be taken by the mouth, it may be given with advantage by the rectum, although he confesses that it is difficult to understand how this action can do great good, except, perhaps, by soothing any intestinal irritation. So far as the treatment of the patient is concerned between the attacks, Brockbank believes that the ingestion of four to eight ounces of olive oil per day will act as the best prophylactic, but appreciates at the same time that few patients would be willing to submit to this treatment without strong opposition. Such patients he believes should receive daily rectal injections of the oil, and if this after a short time becomes so disagreeable that the patient rebels, he thinks that a favorable influence can be exercised by ordering a diet containing large quantities of fat. It would also appear from his experiments that oleic acid is a valuable drug for internal administration under these circumstances. He is unable to discover that turpentine, ether, or chloroform have any direct effect upon the stone, and believes that any advantages obtained by their use are due to the antispasmodic influence. In those cases where a cholecystotomy has been performed and in which a calculus cannot be felt, yet in which the physician is positive a calculus exists, Brockbank suggests the daily injection into the gall-bladder of olive oil or of one-half-per-cent. solution of watery solution of animal soap of the British Pharmacopœia. This treatment he believes can do no harm, and may be advantageously substituted by a similar injection of oleic acid. On the other hand, chloroform, turpentine, and ether, if so used, might produce a dangerous amount of irritation.

From a comparatively limited experience, we are inclined to endorse everything which Brockbank has advised in connection with his useful clinical and experimental research, particularly in regard to the employment of phosphate of sodium as a prophylactic, given in the dose of from 2 to 4 drachms, or more, in hot water every morning before breakfast. We have certainly seen this treatment result in the passage of large amounts of what might be called hepatic gravel, and in the great amelioration of the attacks both in severity and frequency. Perhaps, by the frequent dislodging of small stones before they are large enough to obstruct the duct, prophylaxis may be accomplished.

Another remedy which, in the hands of some practitioners, has given good results, it is claimed, is the succinate of sodium, 5 to 20 grains three times a day. So far as we know,

its employment is purely empirical, and there are no scientific studies which would indicate that it has any particular value.

To those who are interested in this subject, Dr. Brockbank's paper will prove of great value. We hope that he will continue his studies, and that others may be stimulated to similar research, in order that more light may be thrown upon this manifestation of perverted hepatic functional activity.

#### *THE ABORTIVE TREATMENT OF GONORRHOEA.*

THE abortive treatment of gonorrhœa—that is, the application of remedies which so modify the disease that it runs its course in a few days or, at most, two or three weeks, in place of the six to ten weeks usually required for cure—is, in one form or another, almost as old as the disease. Until discovery of a specific germ, and hence power to distinguish in the earliest stages gonorrhœal urethritis from simple inflammatory attacks due to mechanical or chemical irritation, or to micro-organisms other than the gonococcus, there was no good reason for believing that treatment was ever successful in aborting gonorrhœa. It reasonably could be claimed that all cases which were cured were not specific in character, and hence would have recovered without treatment in a few days.

Since the general recognition of the gonococcus as the causative agent in gonorrhœa it is easy to determine whether or not abortion of the disease is ever possible, for this micro-organism is readily stained, is easily recognized by even an indifferent microscopist, and on careful search can be found even in the earliest discharge. Though it has been proved that there is a pseudo-gonococcus present in the normal urethra which can be distinguished from the gonococcus only by culture, this is so rare that its presence need not be considered, and we can safely assume that when a urethral discharge contains gonococci, the disease is certainly gonorrhœa; that if it is a first attack, and is not treated, running will become profuse, will continue for six to ten weeks, and will be accompanied by ardor urinæ, chordee, and possibly symptoms of acute posterior urethritis. If, under any treatment, attacks of urethral inflammation, the discharge of which shows the presence of gonococci, are cured in three days to fourteen or twenty-one weeks, it is safe to assume that treatment is responsible for this cure and that the disease has been aborted or

materially shortened. As the case stands to-day, then, all that is needed to prove that gonorrhœa can be aborted is a record of cases contributed by a conscientious observer, in which, before treatment was begun, gonococci were discovered in the discharge.

Diday records many successful attempts at abortive treatment, but unfortunately omitted to prove by the presence of the gonococci the specific nature of the urethritis. The absence of microscopical examination discredits his results from a scientific stand-point, since he applied his treatment particularly to those cases in which the early symptoms suggested rather simple irritation than gonococci infection. Diday held that an abortive injection must be practised as early as possible, and that the favorable time is when the slight secretion is scarcely colored and more mucous than purulent, and when the lips of the meatus are not swollen. His abortive injection is a five-percent. solution of nitrate of silver, only the fossa navicularis being subject to treatment, the finger pressing the urethra so firmly one and a half inches back that none of the fluid can pass behind this point. This lotion is injected under pressure, so that all the folds and follicles of the navicular fossa are distended.

Though Diday's results can be questioned because of the lack of examination, others have followed his methods and have obtained satisfactory results. Thus, Edward Martin reports the Diday abortive treatment in eight cases. In seven of these gonococci were found. In six of the cases the patients were well in the first ten days, and there was no recurrence of discharge. This percentage of success is probably considerably higher than that obtained by others, since there have been few reports favoring Diday's method, though undoubtedly it has been tried by many.

A reason for failure of this method in a large proportion of cases is given by Janet, who holds that not only do the gonococci quickly penetrate to the subepithelial tissues, but that they rapidly spread along the urethra, so that by the fourth day of the attack this entire channel is often infected, the inflammation involving the posterior as well as the anterior urethra. Hence any treatment limited to the first one or two inches of the urethra will, in the large number of cases, prove fruitless.

The method of attempting abortion by frequent injections of weak antiseptic lotions, such as nitrate of silver, corrosive mercuric chloride, or mercuric salicylate, has also given many satisfactory results, since thus the superficial microbes are destroyed and the whole

mucous membrane is washed out. This is the method which Janet strongly favors, though he abandoned it for one which he describes at length, and one which, if his statistics are correctly reported, is destined to radically change the treatment of gonorrhœa.

This consists in injections of permanganate of potassium. Janet reports, of twenty-one cases in his first series of attempts at aborting gonorrhœa, thirteen were successful and eight failed; the failures he attributes to imperfect technique. The second series of fifteen cases resulted in thirteen successes. In eleven of these the cures were very rapid.

His method is as follows: In the first place, careful search must be made for the gonococcus; next it must be determined whether the inflammation is anterior, total, or extra-urethral. The diagnosis of anterior and posterior infection is made by means of the urine passed in two portions. If the second portion is perfectly clear after the patient has remained for a long time without urinating, it is quite certain that the posterior urethra is not involved. When the second portion contains pus, diagnosis of posterior urethritis is assured. During the whole treatment the second portion of water should be examined, since, even though on first examination the posterior urethra is free, it may subsequently become infected. Extraurethral crypts, in which the gonococci may be numerous, are always seen in cases of hypospadias, and are frequent in those who have an apparently normal meatus. They are readily found on separating the lips of the meatus, and are placed at the upper commissure. These extraurethral foci of infection should be carefully disinfected during the entire course of treatment, either by thoroughly washing or by more radical surgical treatment. Preputial folds should be washed out after each treatment and as often as possible between treatments. Vegetations should receive surgical attention before beginning treatment. Crypts of the meatus are washed by means of a fine canula, if they are wide and shallow; if they are narrow and deep, they should be opened, so that they communicate freely with the meatus. Abscesses, if present, should be opened and disinfected.

As to the condition of the urethra which allows of abortive treatment, the quantity of the discharge has little reference to this. The only condition which should prevent an attempt is in the case of hyperacute inflammation, great swelling of the urethra and meatus, painful erections during the night, and violent ardor urinæ, since under these circumstances

the treatment is painful, penetration of the lotion difficult, and hemorrhages are free. When applied to cases which have already reached this acute stage, the treatment cannot be called abortive.

A rubber siphon about three yards in length is attached to the reservoir. To the extremity of this tube is fixed a blunt conical glass nozzle, of such shape that the urethral orifice is entirely closed when the nozzle is applied. A hard rubber stop-cock is employed. The stop-cock, nozzle, and lower extremity of the tube are kept soaking in antiseptic solution. When the anterior urethra is to be irrigated, the reservoir should be elevated about one and a half feet; when the entire urethra is to be washed out, the elevation should be from three to five feet. The rapidity of flow is regulated by digital pressure exerted upon the soft rubber tube. Where the patient is extremely sensitive, or the resistance of the compressor urethræ muscle is unusually obstinate, cocaine may be used. This drug is introduced by means of a small syringe holding three drachms, the patient being directed to make an effort as though he were about to urinate as the injection is forced in. This allows it to penetrate into the posterior urethra and to anæsthetize this portion of the tube. The solution is held in the urethra for a few minutes; provided it is not of greater strength than one-fourth of one per cent., there is no danger from toxic effects. Permanganate solution should be warm, and the irrigation should be made immediately after urination. The patient having micturated, the glans and prepuce and crypts and follicles in the anterior urethra are thoroughly washed by means of a stream flowing through the glass nozzle. Finally, this nozzle is held firmly in the meatus and the bladder is filled. This backward flow into the bladder is encouraged by directing the patient to make efforts at urination. As soon as he feels an urgent desire to accomplish this act, the nozzle is withdrawn and he is encouraged to do so. If necessary, the bladder is again filled. The patient is then directed to change his linen, to wash his prepuce and glans with a solution of permanganate (1 to 2000) at least once between the irrigations, after micturition, and sometimes it is well to pack the meatus with absorbent cotton.

As to the strength of solution, it is almost impossible to determine what will be appropriate for any individual case. This must depend upon the intensity of the reaction. The more marked the inflammatory symptoms the feebler should be the dose, and *vice versa*. The indications as to inflammatory reaction are found in the ap-

pearance of the meatus, in the amount of discharge, and in the pain connected with urination. When the inflammatory symptoms are pronounced, 1 to 4000 is the proper strength with which to begin; if the symptoms are of moderate severity, 1 to 2000; if inflammation is practically wanting, 1 to 1000.

It should be borne in mind that with the same dose quite different effects can be produced, depending upon the manner in which the solution is applied. Irrigation with a weak solution, conducted slowly, the bladder being filled several times, produces the same effect as a strong solution irrigated rapidly, only a small quantity of liquid being employed, and, *per contra*, an irrigation of 1 to 2000 made with a pint, and filling the bladder but once, has no more marked effect than a full dosage of solution 1 to 4000. As to the repetition of the irrigation, this varies according to the intensity of the gonorrhœa. The more acute the latter the more frequent should be the irrigation. In subacute and chronic cases, once in twenty-four hours is sufficient. In acute cases, once every twelve hours, continued for two or three days; then once every eighteen hours until about the sixth day; then about once in twenty-four hours is sufficient. When two irrigations are made the same day, the second should always be with a weak solution.

Janet gives two tables of treatment: one for the abortive treatment of anterior urethritis, in which he begins with a strength of 1 to 4000, and on the eighth day finishes with a strength of 1 to 500; the second, in which he begins with the same strength; on the fifth day uses 1 to 1000 to the anterior urethra, 1 to 2000 to the posterior; on the eighth day uses 1 to 500 to the anterior, 1 to 1000 to the posterior. He holds that 1 to 1000 is as strong a solution as should ever be used to the posterior urethra, since 1 to 500 employed here will produce painful tenesmus. In the first few hours following irrigation there is a whitish secretion, followed by clear serum, sometimes slightly blood-stained; then absence of secretion; finally, reappearance of purulent discharge, together with the gonococci. The return of purulent secretion is an indication that the effect of the irrigation has passed off; hence these washings should succeed each other so rapidly that this recurrent purulent discharge should be entirely prevented,—that is, the second irrigation should be given during the dry period occasioned by the first irrigation.

As to the question of predicting a cure, this is difficult. Usually ten or eleven washings will be sufficient to bring about abortion. At

this time there is no discharge and few or no shreds. Sometimes there is a little mucous discharge, especially if a strong solution has been employed. In this case irrigations are stopped, the patient is advised to continue hygienic directions, and is told to report immediately on the first sign of white discharge. In the absence of this he appears eight days after the last irrigation.

If recurrence takes place, the discharge usually appears the second or fifth day after the last washing. Janet states that this happened in three out of fifteen cases; the first time because a focus of infection near the frænum was neglected, the last two times because a posterior urethritis was not suspected and received no treatment.

In case of recurrence the irrigations are again administered; sometimes two or three are sufficient; sometimes it is necessary to give the complete series. When the patients are cured, eight days after irrigation there will be found a non-inflammatory meatus, entire absence of discharge, and absence of shreds in the urine. For the next two months such a patient is peculiarly susceptible to renewed infection.

When, in spite of this treatment, there is slight mucous discharge, Janet advises irrigation of the anterior urethra with nitrate of silver (1 to 2000). The details of fifteen cases are given,—nine cases of anterior urethritis, six of total urethritis. The discharge when first observed varied in age from a few hours to five days. Two complete failures marked this series,—one because of the acute inflammation already developed when the patient came under observation and because of a diverticulum at the meatus, which was not divided; the other because of soft chancres which prevented thorough disinfection of the prepuce. There were three partial successes—that is, cure in thirteen, twenty-five, and thirty-eight days respectively—and ten complete successes.

Janet holds that permanganate has a peculiar action on the urethra. It occasions a slight œdema of the urethra; while this lasts not a single microbe can be found in the secretion. The success of the permanganate treatment seems to show that the microbes are so influenced by the alteration of their culture ground, dependent upon the œdema, that they cease to grow; hence if this condition of the urethra is sufficiently maintained, the complete destruction of the microbes is sure. It therefore follows that for successful treatment it is necessary to continuously keep the mucous membrane in a certain condition of reaction. Carried too

far, the growth of the microbe is encouraged; not carried far enough, inhibition ceases. This special reaction is fugacious in proportion to the acuteness of the gonorrhœa; hence the necessity for frequent repetitions of the injections. The special skill in treating this disease depends upon recognizing the required condition of reaction, and in so tempering the strength and the frequency of treatment that this condition is maintained for several days.

The advantages of this abortive treatment are well summarized by Janet. In case the anterior urethra alone is affected absolutely, no pain is excited; often when the entire urethra is washed, the pain is slight and fugacious. No injurious reaction is exhibited on the part of the urethral mucous membrane, as shown by the almost complete absence of epithelial exfoliation. Discharge almost entirely ceases from the first treatment, and in eighty per cent. of cases the treatment will be successful. The objection to the treatment is that it is troublesome for both the patient and the physician.

---

#### HEMORRHAGIC GLAUCOMA AND ITS TREATMENT.

---

EXTRAVASATIONS of blood into the retina, often indicative of arterio-sclerosis in general, or, in particular, of a more definite disease,—viz., malaria, gout, rheumatism, chronic heart lesions, Bright's disease, diabetes, syphilis, and affections of the liver- and blood-manufacturing glands,—are signs calling for critical scrutiny of the functions of the entire organism. In a certain number of these cases the hemorrhages are not only the indices of serious constitutional disturbances, but are also the precursors of sudden rise of tension, or a type of glaucoma, that, so far as vision is concerned, presents a singularly gloomy outlook. In fact, among the various diseases of the eye, during the course of which there may be the development of secondary glaucoma, none is fraught with graver prognostic apprehension than retinal hemorrhages. Hence an analysis of the opinions and experiences of the best-informed surgeons, as well as added personal experience, is of the utmost importance.

This, fortunately, has recently been accomplished by Bourgon, in France (*Annales d'Oculistique*, March, 1893), and Risley, in this country (*Ophthalmic Record*, December, 1893), and it is to the paper of the latter surgeon we direct attention as an excellent review, written in a judicial spirit, of the measures suited to the management of this serious ocular disease. Al-

though never a frequent disease, occurring once in about seven thousand cases, according to Bourgon, and four times among twenty thousand cases seen by Risley, its unfavorable prognosis, not only, as Wadsworth puts it, "as to sight, which is practically gone before the glaucoma appears, but as to the existence of the organ," renders welcome all fresh information on this topic.

Following Bourgon, Risley divides the disease into the hemorrhagic period and the period of confirmed glaucoma. During the first period the evident indication is to ascertain, if possible, the cause of the retinal extravasations and to treat the existing diathesis, whatever that may be, particular attention being paid to the two most probable factors determining the hemorrhages,—viz., changes in the composition of the blood and tissues of the blood-vessel walls and disturbances of the circulation. For this purpose we naturally turn to iodide and bromide of potassium, iron, bichloride of mercury, arsenic, quinine, ergot, cardiac sedatives, salines, and various mineral waters, according to the indications. Having some direct influence upon choroidal congestion, ergot and bromide of sodium should receive special mention. The diet is of much importance, and a regimen suited to a uric-acid diathesis, or positive gouty dyscrasia, will, in most instances, be advisable. Absolute rest for mind, eyes, and body is of paramount importance, and the use of tinted protective glasses is evidently indicated. Depletion from the temple by leeching is a valuable adjunct, and of marked service, or certainly a safe practice, is the twice-daily instillation of a solution of the sulphate of eserine ( $\frac{1}{4}$  grain to 1 fluidounce), to which a few grains of boric acid and one grain of cocaine may be added. Such careful and systematic medication may be the means of preventing rise of tension, and is, perhaps, one of the reasons why the complication is fortunately of comparatively rare occurrence.

If, however, in spite of treatment, or without it, glaucoma supervenes, and of an inflammatory type, the question of operative interference is difficult to decide, from the well-known fact that measures—e.g., iridectomy—usually productive of relief in primary glaucoma, in this disease only too often precipitate blindness by encouraging fresh hemorrhagic extravasations. Bourgon details the results of iridectomy in twenty-four cases, as sixteen failures and eleven enucleations, and in a circular letter addressed by Risley to a number of American ophthalmic surgeons, the opinions were in practical unanimity as to the in-

advisability of iridectomy. Posterior sclerotomy, on the whole, offers a more favorable outlook, although, as Hotz remarks, usually "no kind of operation will save the eye," and the relief of tension and pain following sclerotomy in most instances is transitory.

Risley's conclusions, after a thorough study of the whole subject, in so far as the management of the period of confirmed glaucoma is concerned, are found in the following quotation: Strong solutions of eserine, frequently repeated, local bleeding, and hot applications to the eyeball give partial but only transient relief. Full doses of hydrate of chloral, having the power to reduce tension, according to Stilling (an observation confirmed by the writer), should be exhibited. Pain and increased tension continuing, paracentesis corneæ may be tried as a temporary measure; and, finally, as a more radical means, sclerotomy or paracentesis of the vitreous chamber. If by the latter operations the tension is relieved and deepening of the anterior chamber is secured, a free anterior sclerotomy, or, if the iris is moderately healthy, a broad iridectomy, may be tried.\*

It will thus be seen that Risley, while leaning towards sclerotomy, is unwilling, in selected instances, entirely to abandon the use of iridectomy. He bases this opinion upon the reports of several cases in which iridectomy gave relief from pain and tension, saving the eyeball, although sight was lost. Necessarily, no surgeon would operate on a case of this character without carefully explaining the exact chances and obtaining consent, in case of failure to secure relief, to perform enucleation or one of its substitutes.

---

#### PEROXIDE OF HYDROGEN IN MEMBRANOUS THROAT-AFFECTIONS.

---

IN the *American Journal of the Medical Sciences* for November, 1893, Dr. Williams, of Boston, contributes a paper upon "The Differential Diagnosis and Treatment of Membranous Affections of the Throat." Under the head of "Treatment" he says, "Chlorate of potassium does not seem to be of service, and in excessive doses may do serious harm. Nitrate of silver does not penetrate deeply enough. Chromic acid is too active. Iodine and bromine are too irritating." The digestives have not succeeded in his hands in removing the membrane. Tincture of the chloride of iron is a useful, but by no means a specific remedy. It does more good when taken internally, probably, than

when locally applied. He finds that corrosive sublimate has an antiseptic rather than germicidal influence in this disease. Thus, while a solution of 1 to 10,000 may stop the spread of the membrane, it does not kill the bacilli. He finds that a solution of peroxide of hydrogen of between twelve and twenty-five volumes killed the bacilli in ten seconds, provided that the reaction was slightly acid; but it required a fifty-volume neutral solution of hydrogen peroxide to do the same work. He points out that the ordinary hydrogen peroxide as found on the market possesses a strength of seven to ten volumes; that some are neutral and others acid. The fact that acid solutions have been found more valuable than neutral ones is interesting, as it has generally been considered that those preparations of hydrogen peroxide possessing distinct acid properties were not therapeutically useful. As a result of his clinical and experimental work, Dr. Williams believes that the solutions of twenty-five to fifty volumes are of value not only through their germicidal influence, but also through their power of breaking up the membrane already formed. The drawbacks to the use of strong solutions of hydrogen peroxide consist in the fact that when acid they cause pain, which, however, lasts but a short time. Strong acidity is not needed. Half per cent. to one per cent. is sufficient. The other disadvantage is that these strong solutions have heretofore not been readily procured and they do not bear transportation well. Dr. Williams states that they can be had, however, by evaporating a ten-volume solution in an open dish over a water-bath until it is sufficiently concentrated. He also reminds us that it is a powerful bleaching agent, and of all substances with which it comes in contact. In many cases it is necessary to make the application every four hours during the night and more frequently during the daytime. The solutions are best applied by means of a swab, fine syringe, or, better still, a spray.

---

## Reports on Therapeutic Progress.

---

### TREATMENT OF RENAL INSUFFICIENCY.

This important subject is discussed in the *New York Medical Journal* by ROCHESTER.

The conclusions to be drawn from the cases he has seen as regards treatment are:

1. We should not try to stimulate into activity an organ that is inflamed or degenerated, by the use of drugs that excite functional ac-

tivity of such organ. In the case of the kidney, we should rarely, if ever, have recourse to stimulating diuretics, or to diuretics which, like digitalis, act by increasing the arterial pressure, until we have relieved the venous congestion by diaphoresis or catharsis, or both.

2. Attention to diet is of the utmost importance in these cases.

3. In order that the materials to be excreted by the kidney may come to that organ in the most unirritating form, the metabolic process should be carried to completion; this is to be accomplished by regular systematic exercise, which is to be obtained by massage when active exercise is not advisable, by inhalations of pure oxygen gas when it is evident that sufficient oxygen is not obtained from the air, and by the dilatation of the katabolic materials by drinking large amounts of distilled water, or one of the mildly alkaline waters, such as Bethesda, Poland, or Buffalo lithia water.

4. The anæmia that accompanies these cases should be met by the use of oxygen and iron.

5. As the symptoms indicative of this condition are the result of toxæmia which depends upon the non-elimination from the body of certain katabolic materials that should normally be carried off through the kidneys, and as these organs are in such condition that they cannot do their work, all other avenues of elimination should be opened up for the escape of these poisons. This is to be brought about by exciting the activity of the skin by means of hot-air or steam baths, accompanied and followed by vigorous massage, keeping the bowels open by means of salines and by washing away the contents of the colon, thus keeping the mucous membrane in a proper condition for excretion, with copious enemata of slightly alkaline water, occasionally followed by a high enema of 500 or 600 cubic centimetres of pure olive oil, as suggested by Fleiner.—*Berliner Klin. Wochenschrift*, 1893, Nos. 3 and 4.

---

### OBESITY TREATED BY AN EXCLUSIVELY NITROGENOUS DIET AND COPIOUS LIBATIONS OF WARM WATER.

SAVILL gives an account of his treatment of cases of obesity in the *Lancet*.

A man, aged sixty-eight, was admitted to the Paddington Infirmary on September 21, 1891, on account of ulcer in the leg. He was about five feet ten inches in height and weighed twenty stone four and a half pounds. His girth was so great that it was necessary to get a special suit of clothes made for him, and he was quite unable to walk, chiefly by reason of his

bulk, but partly also because of stiffness of the hip-joint due to morbus coxæ senilis. There were also a suspicion of chronic Bright's disease and a history of gout.

He had formerly (from August, 1890, to February, 1891) been under the writer's treatment, on the same plan as the one about to be described, for obesity and ulcer of the leg. While in the infirmary on that occasion his ulcer had healed and his weight had been reduced from twenty-one stone to seventeen and a half stone; but a month or two after leaving his leg again became ulcerated and his bulk again began gradually to increase.

Stoutness had run in his father's family and his father had been as corpulent as himself, but his mother and her people were all small. As for the patient, he had lived an abstemious life, though he had been in the habit of drinking one or two pints of beer a day with his meals, and had worked hard as an engine-fitter all his life. He had been stout as a child, but at the age of twenty-one he weighed only twelve stone, and, though always rather bulky, had but recently been unable to work on account of his size.

He was at once put upon a diet consisting of one pound of cooked fish and one pound of cooked lean meat daily, with a pint of warm water sipped at intervals, as warm as he could comfortably drink it, every two hours. The fish and the meat were distributed into various meals, according to the taste of the patient, but no bread and vegetables, milk, or any other article were allowed. He was an intelligent man, and entered heartily into his treatment,—a most important factor in success. He managed to drink about five or six pints of warm water in the day. His weight began at once to fall steadily. Thus, on September 21 it was twenty stone four and a half pounds; on October 2, nineteen stone eight pounds; on November 18, eighteen stone four pounds; and on December 4, seventeen stone eight and a half pounds. About Christmas time his dietary was a little relaxed, and he immediately went up seven pounds, but by January 15 he was reduced again to seventeen stone one pound.

After about four months' treatment, in January, 1892, he began to rebel a little, and the diet was modified by the addition of two small slices of bread and butter with breakfast and tea, and the addition of milk and sugar to his tea in the morning and evening. Nevertheless, the weight still continued to diminish (February 7, sixteen stone seven pounds). On February 7 he returned to ordinary meat diet,

such as the other patients had, with the omission of potatoes. At first the weight went up a few pounds (sixteen stone ten and a half pounds), but then the downward course was resumed, and on March 21, 1892, he weighed sixteen stone six and a half pounds. He then left the infirmary to return to work, having lost nearly four stone in six months, during four months of which he was on a strictly nitrogenous diet, and for one and a half months of which he was on ordinary diet, without potatoes.

His ulcer was healed within a month of his admission, and he began to get up and about, taking as much exercise as the ward space allowed; and, although he took no medicine excepting an occasional aperient, the pain and stiffness of the hip-joint soon disappeared. He passed large quantities of urine of low specific gravity, which very frequently contained crystals of uric acid. Dr. Haig's valuable observations on the urine are appended. Once only it contained a trace of albumin (November 6, 1891). Subsequent observations show that, though he takes ordinary diet, avoiding beer, he keeps at about sixteen and a half stone and in good health. He continues to take draughts of warm water when circumstances allow.

The rationale of this treatment is apparently that the patient supplies the necessary hydrocarbons and carbohydrates, which are absent from the diet, from his own economy; in other words, he lives on his own fat. Dr. Lloyd suggested this treatment to the author. It is something like that adopted by Marienbad. It was certainly very successful in this case, for the man was not only thinner, but was in much better health in every way and able to resume work. The permanence of the improvement after resuming ordinary diet is a fact worthy of special attention.

It is useless to attempt the regimen without the hearty co-operation of the patient. In another case, weighing seventeen and a half stone, in the same ward as this patient, the same treatment failed because he would not carry out the dietary. The copious libations of warm water are probably of great importance, and the patient probably retains his decrease in weight owing to this avoidance of beer and the taking of warm water.

Dr. Haig says he hoped to discover why obese patients, when put on an exclusively animal diet, rarely suffer from attacks of gout, though in ordinary dietetics any excess in meat food has such a powerful influence in producing this disease.

The following are some of the results ob-

tained from an examination of the urine of the twenty-four hours ending 8 A.M. on December 21, 1891, when the patient was on the special diet and had been on it for three months. That of twelve hours of the day was dark amber and measured forty-four ounces; that of the night was pale amber and measured seventy-four ounces; the mixture—one hundred and eighteen ounces—was pale amber, free from deposit, of specific gravity 1012, and containing no albumin. This yielded 1.5 per cent. of urea (equal to 817 grains) and .04704 per cent. of uric acid (equal to 25.5 grains), giving a relation of uric acid to urea of 1 to 32. On examination on other occasions, between 800 and 900 grains of urea and about the same proportion to it of uric acid as that above given was found, and there was no evidence that he was retaining any large quantity of uric acid. His weight at that time was about seventeen stone twelve and a half pounds, so that his excretion of urea was about 3.4 grains per pound. An examination of the urine of the twenty-four hours ending February 10, 1892 (being the urine of the second day on ordinary diet), gave the following results: Day urine, thirty-four ounces; night urine, seventy-two ounces; together, one hundred and six ounces; pale amber in color; specific gravity 1010, and containing a trace of albumin; urea, .95 per cent. (equal to 465 grains); uric acid, .03696 per cent. (equal to 18 grains); relation of uric acid to urea, 1 to 26 (nearly). His weight is now sixteen stone seven pounds, and the urea is, therefore, equal to two grains per pound, and the excretion of uric acid has decidedly increased. The specific gravity of the urine was always low, and it was scanty by day and profuse at night. His pulse, whenever examined, was below 70 in rate and of distinctly high tension. It will be noted that 3.4 grains of urea per pound is just below the normal physiological quantity, and though, no doubt, something must be allowed for his adipose tissue, Haig has under his care a man of less than half his weight who is on a highly nitrogenous diet for diabetes, but who still probably takes less than hundred grains of urea, or about seven grains this man, yet he often passes upward of eight per pound; so that, even if it is admitted that the large quantity of fluid taken did to some extent interfere with digestion, and a further large allowance is made for adipose tissue, the urea was still very low, considering the diet. Even on the purely animal diet the acidity of the urine was low and he retained but very little uric acid; but had this same diet been given to a younger man without Bright's disease, and

with more active metabolism, the urea would have been more like eight to ten grains per pound, the acidity would have been higher and the uric-acid excretion much less (in relation, say, of 1 to 40 or 1 to 50). He would have retained and accumulated much more uric acid, and, as a result of this, would soon have suffered from gout. So far, then, as one can judge from the results in a single case, it is the extremely low metabolic activity in such patients that prevents their accumulating uric acid and suffering from gout. The patient under notice, if the history may be trusted, suffered pretty severely from gout in the feet in previous years, but when he became obese and unwieldy, and consequently unable to work, his metabolism, urea, and acidity rapidly fell, and he continually excreted an excess of uric acid from his joints in place of storing it in them; hence he lost his gout, but acquired uric acidæmia in its place, and this still further hampered metabolism and produced Bright's disease. So, when he came under observation, he was constantly excreting excess of urate and had no gout, and even the stimulus of the animal diet was insufficient to reverse the process or to cause a storage of urate and a relapse of his gout.

#### *A CASE OF POISONING FROM AN OVERDOSE OF CODEINE.*

In the *New York Medical Record*, SPRATLING details a case of codeine-poisoning.

Shortly after ten o'clock on the evening of June 8 the author was requested to see a young married woman who had taken an overdose of codeine. Immediately after dinner, about seven o'clock in the evening, she had taken sixteen  $\frac{1}{2}$ -grain pills, making eight grains altogether. She had suffered for some months from a painful disease, and had been ordered by her physician to take codeine in  $\frac{1}{4}$ -grain doses for the relief of pain and to overcome a persistent insomnia. Not deeming the  $\frac{1}{4}$ -grain pills of sufficient strength, the patient then procured from the druggist a vial labelled as containing one hundred  $\frac{1}{2}$ -grain codeine pills. Three hours before the author's visit she had swallowed sixteen of these, as she avowed, for the purpose of securing a good night's sleep. An hour later she experienced considerable nausea, and vomited a small quantity of semi-liquid matter. He found her awake, able to converse well, but extremely restless and irritable. She could not lie in one position, but constantly changed it by tossing, almost violently, from side to side of the bed. At frequent intervals she would manifest convulsive movements, involving the

entire voluntary muscular system. These movements were most marked in the upper extremities and the head. She suffered greatly from intense irritation of the skin over the entire body. This irritation was most annoying along the flexor surfaces of the forearms and on the back. She had an attendant rub her back so vigorously with a coarse towel that the skin in many places was broken. The surface of the body was warm and dry. The pupils were fixed in pin-point contraction. Respirations were 12 per minute. She complained of great thirst and an uncomfortable feeling of fulness in the head. She did not experience the pleasant effects following the exhibition of morphine. She frequently remarked that her "thoughts were going round and round." After the painful irritation of the skin had been relieved by sponging the body with solution of bicarbonate of sodium, she sank into a light doze, from which she would awake in a few minutes with a start. The skin was hyperæsthetic to a marked degree. She was subjected to the usual treatment for opium-poisoning, and in a few hours was much improved.

By noon on the following day she had entirely recovered from the effects of the drug in every way, save that considerable muscular weakness remained. We apparently have no fairly accurate knowledge as to what amount of this drug may be regarded as a fatal dose. In the latest edition of Wood's "Therapeutics" it is stated that "Robiquet, in a series of experiments, found that doses of .01 to .03 gramme (.15 to .46 grain) produced a feeling of contentment, calmed nervousness, and induced refreshing sleep, while .1 to .2 gramme (1.53 to 3.07 grains) caused deep sleep, followed by nausea and vomiting." Quoting further from the same author, he adds, "Dr. A. S. Myrtle records a case of severe poisoning by 4 grains of codeine. And Dr. D. Walsh reports serious poisoning by 8 grains of codeine."

*CLINICAL REMARKS ON CERTAIN  
CHANGES OBSERVED IN THE  
URINE IN MYXŒDEMA AFTER  
THE ADMINISTRATION OF  
GLYCERIN EXTRACT OF  
THYROID GLAND.*

DR. ORD and MR. WHITE publish in the *British Medical Journal* a careful clinical observation on the effect of thyroid extract upon the urinary secretion in myxœdema.

A patient suffering from myxœdema was admitted to St. Thomas's Hospital on April 19,

1893. After careful daily examination of the food and the urine, she began, on May 1, to take 20 drops of a glycerin extract of the thyroid body of the sheep daily. The dose was equivalent to a sixth part of the whole thyroid body of the sheep.

For a week previous to May 1 the patient had been placed on a diet carefully ordered, so that its elements should be as much as possible the same day by day. The particulars of this diet and its equivalent in chemical examination will be published subsequently. The same diet was maintained after the administration of the thyroid extract during the whole period of the treatment of the patient in hospital.

After the administration of the thyroid extract a marked change was observed both in the volume of urine passed and in the quantity of nitrogen excreted. An increase in the volume of urine is the first point to be noted. As regards the excretion of nitrogen, the quantity up to the time of the administration of the thyroid extract corresponded fairly with the amount of nitrogen taken in the food, being, as one would expect, slightly less. Bearing in mind this fact, that before treatment the nitrogen excreted in the urine was slightly less than that taken in the food, it is of importance to note that three days after the first administration of the thyroid extract the excretion of nitrogen in the urine exceeded the amount introduced in the food, and that this proportion, very much marked in the earlier days of treatment, was practically maintained so long as the patient was under observation.

The total nitrogenous excretion was determined, as well as the excretion of urea, in order to ascertain whether the nitrogen might be excreted in any form other than urea. The records show that the relation of total nitrogen to nitrogen as urea remained about the same as in normal urine, thus indicating that the nitrogen was still excreted chiefly as urea. It was also seen that the difference between organic matter and urea remained about the same during the continuance of the experiment, thus showing that, in addition to water, the increased excretion was urea or other nitrogenous matter. At the same time it is important to notice that the patient lost weight rather rapidly in the first week of treatment,—namely, from eight stone four and a half pounds to seven stone thirteen pounds, with a further but more gradual loss of three pounds. The temperature of the body was raised; before treatment it had been sub-normal, ranging from 96.6° to 98.6° F., ranging afterwards from 97.6° to 100° F., the maximum temperature being reached on the thir-

teenth day after treatment had begun. As regards the loss of weight, we have to take into account the fact that the patient, having previously a very dry skin, had free perspiration after the administration of the drug.

With regard to the excretion of inorganic matter, it had occurred to them that, with the increased excretion of urea and the associated rise of temperature, changes in the excretion of saline matters, such as occur in pyrexia, might be looked for. It appears, however, that in this case the excretion of the inorganic substances determined was very little affected by the thyroid treatment.

The acidity of the urine was observed to follow closely the variation in the quantity of phosphoric acid eliminated, thus being evidently due to acid sodium phosphate as in normal urine. It is to be regretted that the sulphates in the urine have not been determined, seeing that they might have shown whether the increased nitrogenous excretion might be referred to destruction of proteid substances or some other form of nitrogenous matter.

The writers present the following conclusions as the result of the treatment and observations in this case:

1. That the urine is increased in volume.
2. That the nitrogen excreted in the urine exceeds the total quantity of nitrogen in the food.
3. The phosphoric acid and chlorine elimination are practically unaffected.
4. That the increased nitrogenous excretion is chiefly in the form of urea.
5. That the body-weight is rapidly diminished.
6. That the temperature of the body is raised.

A chart is appended showing the changes in the weight of the body, the nitrogenous value of the food taken daily, and the excretion of nitrogen after treatment.

They propose, also, to publish later a full report of their observations, with the tables illustrating them.

#### THE THERAPEUTICS OF LUPUS VULGARIS.

HOFRATH D. VEIEL (*Berliner Klinische Wochenschrift*, No. 39) describes the manner in which he uses pyrogallol for the treatment of lupus vulgaris. The first treatment consists in the destruction of such lupoid tissue as is visible and can be felt. For this he chooses his method according to the locality and variety of the lupus, sometimes a mechanical treatment

(scarification, scraping off), sometimes a chemical one (caustic potash, or nitrate-of-silver pencil, or pyrogallol vaseline, ten per cent.), sometimes a thermic treatment (thermo-cautery, galvano-cautery). When the pyrogallol cannot be used alone from the first, he uses a bandage of ten per cent. pyrogallol vaseline salve spread on lint. The first bandage is left for two days; from the third day on the same dressing is renewed once a day. In this manner he seeks fully to destroy any lupus particles which may have escaped the first treatment. This is quickly accomplished. It is advisable to protect the surrounding healthy skin by a plaster (for example, of zinc benzol salve on mull) from the action of the pyrogallol, which produces a very painful irritation.

On the fourth or fifth day the application of the strong pyrogallol is usually exceedingly painful, so that in many cases morphine injections become necessary. An addition of cocaine to the salve did not prevent the pain. The pain is most severe upon the entrance of air when the bandage is moved or opened. The change of bandage should be made as quickly as possible and very carefully applied. When this pain occurs it is time to leave off the strong salve and take another course. Formerly the healing was obtained under vaseline or iodoform, but Veiel now uses a weaker pyrogallol salve, which does destroy the lupoid tissue, but does not prevent the formation of healthy granulations. The two-per-cent. salve usually fulfils these conditions. If this is too strong, a one-per-cent. may be used, or even a .5- or .2-per-cent. may be used as soon as the granulated surface is formed.

The healing is usually very slow by this method, but the scars are smoother and prettier than by any other method of treatment. Therefore he uses the pyrogallol when the face or any part is affected, where a pretty scar is desirable. When this is no object, he uses transplantation after Thiersch's method as soon as the smooth granulated surface is formed.

The urine must be constantly watched during the treatment, and the use of pyrogallol at once stopped if albuminuria or hæmaturia occurs. Veiel has never in all the cases treated seen any permanent action upon the kidneys or general health, no doubt because the pyrogallol is used on comparatively small surfaces.

The good results in tuberculosis of the skin led him to try the pyrogallol also for that of the bones. In tuberculosis of the hollow bones it was without result, but cured four cases of caries of the tarsal bone. They were treated during two weeks with the ten-per-cent, and then until

cured with two-per-cent. salve. The cure took from eight to thirteen weeks.

He used a .5-per-cent. watery solution of pyrogallol for a girl who had lupus of the conjunctiva, dropping it in the eye daily. She has now been well for a year.

#### THE TREATMENT OF ACTINOMYCOSIS OF THE JAW.

A new case showing the efficiency of potassium iodide in the treatment of actinomycosis has been recorded quite recently by F. BUZZI and B. GALLI-VALERIO (*Nouveaux Remèdes; Journ. de Médecine de Paris*). The case occurred in a young man who contracted the disease while farming. The malady began by a localized pruritus on the external surface of the gums, invading afterwards especially the gum of the last right superior molar tooth. The patient sought to relieve the itching by scratching with a straw. The gum became tumefied, this tumefaction invading little by little the parotid and masseteric regions, all of the right cheek, the eyelids, the mastoid region, and the right half side of the neck just over the clavicle. The real nature of the disorder was not recognized at first. At the beginning the tumor was not painful and presented several fluctuating points. These purulent foci were opened; but, notwithstanding the cleansing of the walls of the abscesses and the irrigations of bichloride solutions, the tumor did not subside and the suppuration continued. Lancinating pains supervened over the neck and back of the head, and there was a slight feverish reaction. Examination of the pus afterwards showed the case to be one of actinomycosis. The patient was, therefore, put under iodide of potassium, in daily doses of 2 grammes. After a few days amelioration was noticeable. The fistulous openings began to close, tumefaction was diminished, and the pain disappeared. In three months more a complete cure was established.

#### A NEW TREATMENT FOR EPILEPSY.

It is believed that a prolonged treatment by opiates renders the organism extremely susceptible to the action of the bromides. This in mind, FLECHSIG, of Leipsic, has administered opium at the beginning of the treatment of epilepsy, in ascending quantities of from 15 centigrammes to 75 centigrammes, and even 1.05 grammes, in three doses, during six consecutive weeks. About this time he has

stopped abruptly the administration of the drug, and prescribed then, during a period of about two months, bromide of potassium in doses of 7.50 grammes, gradually reducing the amount to 2 grammes per day. The convulsive seizures disappeared as if by magic on the suspension of the opium and the beginning of the ingestion of the bromide of potassium. This instantaneous effect was produced in two patients of the author, in whom all other medication employed for several years had utterly failed to do any good.—*Gaz. Méd. de Liège; Journ. de Méd. de Paris*.

#### CHLOROFORM NOT CONTRAINDICATED IN KIDNEY-DISEASE.

An interesting case of albuminuria is recorded by POITOU-DU-PLESSY (*Journ. de Médecine de Paris*), in which chloroform produced no evil effects. A woman in labor, and who had previously showed unmistakable evidence of albuminuria (from .40 to 1.30 grammes of albumin in the litre of urine), had to be anesthetized in order to subdue the intense pains and the over-excited nervous system. A mixture of bromide of ethyl and chloroform was employed for the anesthesia, the patient getting in all about twenty-five grammes of the ethyl bromide and eighty grammes of chloroform. The anesthesia was complete, and the woman safely delivered of twins. The first analysis of the urine, soon after the confinement, showed that the albumin had almost entirely disappeared, only traces of it being detected. The author refers also to another case,—this one evidently of cystitis,—occurring in a man seventy-seven years of age, who was operated on for stone in the bladder, and in whom the chloroform anesthesia lasted for fully one hundred and ten minutes. No untoward after-effects were observed. He believes, finally, that chloroform, judiciously and methodically administered, exercises no noxious influence on the kidneys, and that no fear should be entertained in regard to its employment in uræmic convulsions where we wish to combat the medullary excitability. Bromide of ethyl he likewise believes exercises a more pronounced action on the medulla and acts even more rapidly than chloroform; therefore, he considers advantageous the administration of a mixture of the two agents for anæsthetic purposes.

#### THE VALUE OF ALCOHOL IN PNEUMONIA.

In the *Boston Medical and Surgical Journal* an interesting account of a discussion on this topic is given.

At the Société de Thérapeutique, session of May 24, 1893, the subject of the therapeutic value of alcohol in pneumonia was again discussed. While the necessity of alcohol in the asthenic forms was admitted by all, the general sentiment of the authorities present was in favor of giving alcohol, as such, in its purity, sufficiently diluted. The old notion that old wines, whiskeys, etc., were to be preferred because of the "mellowing" properties conferred by age was condemned as a delusion. Such liquors were declared to be much more irritant to the stomach and less certain in their general supporting effects than pure ethyl alcohol, deprived of aroma.

One eminent speaker commended the alcohol of rice as being exceptionally free from fusel oil and other impurities.

We are told that the best French cognac is, "with few exceptions, nothing but the alcohol of beets, of poor molasses, changed and colored by the fabricator by the addition of infusion of tea and various essences which give it bouquet." Such brandies are almost sure to contain methyl alcohol in quantity certain, when freely administered, to do harm to the patient.

M. Huchard, who is an enthusiastic advocate of the employment of digitalis in the pneumonia of influenza, thinks alcohol the remedy *par excellence* of pneumonia by reason of its "dynamogenous action." There was much speculation as to how alcohol does good. M. Bovet declared somewhat vaguely that "by its dynamogenous action it supports the patient; by its reducing action it modifies the elements of the blood, which, rendered more fluid, undergoes an osmotic acceleration which expresses itself by the progressive decongestion of the pulmonary parenchyma." He also thought that "by its calorigenous reaction it develops a considerable number of calorics which cannot but have an influence on the evolution of the infectious elements, by this fact impeded in their toxic action and possibly destroyed. "What tends to prove this," he says, "is that, after the absorption of the alcohol, we find in the extractive matters of pneumonia patients an abnormal proportion of waste matters of the creatinic series, which are known to be endowed with a remarkable toxicity."

But, apart from such speculations, the best proof of the value of alcohol in pneumonia was affirmed to be clinical experience.

The combination of pure ethyl alcohol with digitalis constitutes, in the estimation of Huchard, the ideal treatment of pneumonia when any active treatment is needed. He gives the digitalis in the form of its active

principle—the crystallized digitalin—in the daily dose of 1 milligramme by mouth.

It is a little singular that no allusion was made at this meeting to the therapeutic efficacy of strychnine in acute croupous pneumonia, a drug which is coming more and more into favor generally as a cardiac tonic in this disease.

#### RECTAL INJECTION OF SALINE SOLUTION IN A CASE OF SEVERE HEMORRHAGE DURING ABORTION.

In the *Lancet*, NICHOLSON details a case benefited by saline injections by the rectum after severe hemorrhage. He was called to see a woman, aged thirty, who had just aborted, the process being accompanied by very severe hemorrhage, which had nearly ceased on his arrival. The patient was the mother of three children born alive; all the labors had been accompanied by severe loss. So great had been the hemorrhage in her last confinement that her medical attendant had warned her against the risk of a further increase in her family. The patient was found in a deplorable condition from the acute anæmia. The pulse was 140 to 150, small, running, and occasionally irregular; the cardiac sounds were faint and the apex-beat imperceptible. She was extremely pallid and restless, and could not get enough air. She complained of nausea, with constant retching and vomiting of small quantities of mucus. Every few minutes she became thirsty and then faint, and was unconscious at times. Notwithstanding treatment by raising the foot of the bed, bandaging the legs, hypodermic injection of brandy, etc., the faintness, sickness, and feeble pulse continued, the patient becoming even more prostrate. After an hour the author determined to try the effect of a chloride of sodium enema, one drachm to the pint of water, at the temperature of 100° F. The patient having had severe diarrhoea, he was afraid the injection would not be retained, but this was successfully accomplished by holding a pad over the anus for a few minutes. The effect was extremely beneficial, for within twenty minutes the pulse fell to 120, the color improved, the sickness and faintness almost entirely disappeared, and she expressed herself as feeling much better and more comfortable. In half an hour she was able to take and keep down a small quantity of beef extract. Shortly after she had a little sleep. The patient made an excellent recovery and was able to be out about a month later. The saline enema in all probability saved the patient's life.

*THE ETIOLOGY AND THERAPEUTICS OF ALCOHOLIC INEBRIETY.*

MASON contributes to the August number of the *Brooklyn Medical Journal* an article upon this subject, and in regard to the therapeutics of these cases believes that much can be done. He points out that Luton, of Rheims, Belgium, was the first to use strychnine in alcoholism; then the Russians used it largely, and it was known as the "Russian treatment;" and, finally, the Americans adopted its use in such cases.

Strychnine has proved serviceable as both abortive and curative in acute alcoholic delirium, as well as useful in the more chronic forms of alcoholism. It seems to be tolerated in such cases. In cases of alcoholic poisoning under normal conditions we have no record of the value of strychnine as an antidote; interesting experiments might be made on the lower animals with the view of determining this point. Strychnine is an excellent cardiac tonic and one of the best respiratory stimulants, and might be used in general medicine in cases in which alcohol is oftentimes prescribed.

Oxide of zinc, during the past twenty years, has been used with advantage in cases of chronic alcoholic intoxication. This drug was largely brought to the notice of the profession by Dr. W. Marcet, of London, who had an extensive hospital and dispensary practice, especially in diseases of the nervous system; and as he found zinc of value in various chronic disorders of the nervous system, he used it also in cases of chronic alcoholism. His observations, published in a small work entitled "Chronic Alcoholic Intoxication," are an extremely valuable addition to the literature of alcoholism.

Quinine has been used more particularly in the later or convalescent period of the treatment of alcoholism.

The so-called "Red Cinchona Cure" for a time interested the public. Rational medicine does not recognize any special drug or specific remedy as a universal cure for inebriety, nor does clinical experience form any basis for such a claim. From the very nature of the case, such a remedy would be impossible. The etiology of inebriety is dependent on such a variety of causes, and its environments and complications are so numerous, that any one remedy could not fulfil all, or even meet the more important, of these conditions. However valuable drugs may be to meet certain indications in the various conditions incident to inebriety, we believe that, so far as

the curative treatment of inebriety is concerned, drugs must assume a secondary place, valuable as they may be in their respective spheres.

In the treatment of the alcohol habit we place, first, restraint and seclusion in a special asylum for a definite period, and total abstinence during this period.

In a few words, concisely expressed, this statement includes the plan now adopted by the leading asylums of this country and of Europe for the recovery of the inebriate. It involves restraint (legal, if need be), seclusion, a special institution in which all the latest and best methods of dealing with the inebriate are procurable, a sufficient period in which to apply these measures, and, we need hardly add, a long period of total abstinence from all alcoholic liquors. Diet, rest, recreation, hygienic surroundings, and the exhibition of appropriate drugs are, of course, all included in the above plan.

The causes of degeneration having been removed and the factors of regeneration brought into action, new formation of nerve, muscle, and tissue must supplant degenerated tissue, if, haply, organic disease has not resulted in irreparable injury.

We have hinted at an hysterical element in the history of inebriety. The inebriate, whatever may be his condition, is largely influenced by his surroundings; hence, as almost in no other disease, must we recognize the value of psycho-therapeutic agencies, hitherto used by the charlatan, but recently recognized and practised by leading neurologists, as of value in their specialty.

In the light of such an historical element in the clinical history of inebriety, we can readily account for the apparent success of the so-called temperance movements that sweep over communities periodically and effect many apparent cures, or rather, in the language of the day, reformations. Such an element will also explain why, after such a tidal wave of excitement, relapses take place oftentimes in large numbers, and the period of excitement is followed by a period of reaction.

The occurrence of relapses is readily accounted for by the fact that the stimulus of the period of excitement buoys up the inebriate for the time being, during which strong mental emotion is a powerful factor. He is keyed up, as it were, for the time, and sustained by a moral stimulus. When this is withdrawn, reaction, followed by corresponding depression, sets in, and the old method of stimulation is again imperatively demanded and yielded to.

Why some inebriates go through such a period of excitement and do not relapse, and why others do, can be accounted for by the fact that the former are in a reasonable degree of physical health, and are not burdened, dragged down, and handicapped either by disease that is non-alcoholic or that is the result of alcoholic degeneration. The inebriates so affected are not influenced, or, if at all, only temporarily, by the so-called "temperance revivals" that appear and disappear with almost stated regularity in large and small communities, and we must add, do good, but only in the channel indicated.

It is by operating through this hysterical feature of inebriety that charlatanism may effect a temporary, possibly a permanent, success in a certain class of cases.

A physician observed to the writer that he had visited many asylums for the cure of the inebriate, and that when the medical superintendents were men of strong will power and personal magnetism, as he expressed it, more cures were effected than when the reverse was true. When the inebriety is due largely to neurasthenia, or in cases where the hysterical element largely preponderates, we believe psycho-therapeutic agencies, or even those that appeal to purely mental conditions, will be of service, but they will not cure a cirrhotic liver, lung, or kidney, or remove the physical causes upon which the inebriety may depend. In addition to those measures that appeal to the higher moral nature, there ought also to be combined such as meet certain intelligent wants. To this end all reasonable amusements, entertainments, and especially such occupations as will interest the person and keep him busy, should be encouraged, if not made compulsory.

Incidentally may be mentioned hypnotism as having been used especially by French physicians, with some benefit in cases of chronic alcoholism. The author has had no personal experience with it.

The therapeutics of inebriety is a new field as yet not fairly occupied, but we believe that the only true road to successful treatment will be along the lines we have indicated,—that is, a knowledge of the underlying causes and the use of such therapeutic agencies as will best remove these.

#### *EPILEPSY CURED BY THE REMOVAL OF PERIPHERAL IRRITATION.*

In the *Edinburgh Medical Journal* for July, 1893, MILLER records the case of a man, aged thirty-two, who was suffering from epileptic fits

preceded by contraction of the flexor muscles of the right arm.

Patient said that five years ago he got a fright, having been arrested by the police in mistake for another person, and that he has been very nervous since then. Ten months ago patient had a quarrel with his parents, and left their house. He was in a state of excitement for some weeks after this, and worked very hard at his carpenter's bench to relieve his feelings. About a month after the quarrel he noticed a contraction in the palm of the right hand. About this time he began to have fits.

Patient gives a good account of his personal history and habits. His family history is good.

Patient looks a strong, healthy man, but is rather nervous and excitable. The right arm fully as muscular as the left, though he uses the latter rather more. Patient says that the right arm does not feel as strong as the left. There is also a "peculiar" feeling in it which he cannot describe. There is slight contraction of the slips of the palmar fascia going to the ring and little fingers of the right hand, felt most distinctly at the transverse fold of the palm. Patient has a contracted prepuce which closely fits the glans penis. He has also a tendency to inguinal hernia on both sides. (Open inguinal canal probably congenital.)

The fits take place mostly at night, after an emission, and about once a fortnight.

If the patient is awake when the fit is coming on he feels dull. The fingers of the right hand become flexed, and the thumb over them; the arm then flexes till the closed hand touches the right shoulder. The right leg then becomes extended and rigid. The toes are not affected. The respiration becomes rapid, patient hears his heart beating violently, and then becomes unconscious.

When he regains consciousness (which is in about an hour) he finds his mouth covered with saliva, he is very weak and drowsy, and usually falls into a dull, heavy sleep. He has usually to take a rest for a day or two after each attack.

Patient says that if, when he feels an attack coming on, he can have his fingers held out straight and his leg firmly flexed, the fit is checked. At such times he feels his muscles working, but nothing more happens. He says also that if he sleeps on his left side he has no fits.

On December 6, chloroform having been administered, Mr. Miller slit up the prepuce and also forcibly stretched the contracted

palmar fascia, and then put on a splint. Patient was also ordered full doses of potassium bromide. He had a slight fit on December 9. Patient went home on January 16, 1892, having had no more fits. He had discontinued the bromide of potassium, but wore a posterior splint on the right hand to keep the ring and little fingers extended.

Patient returned some months after and reported himself quite well.

This case seems to show an interesting sequence of events. The man was arrested on suspicion and shut up in jail for a night, having been mistaken, he says, for another person. This gave him a great fright, and ever since then he has been nervous and excitable. Ten months before the commencement of the fits he had a quarrel with his parents and left their house. He was much excited at this time, and remained in a state of excitement for two or three weeks, during which time he worked very hard to relieve his feelings. Being a carpenter, the nature of his work obliged him to use his right hand a great deal, and at the end of this period he noticed for the first time a hardness in the palm of the right hand and a contraction of the ring and little fingers. About the same time he had his first fit one day when putting on his coat. After that he had recurring epileptic fits about once a fortnight for nine months, occurring sometimes at night after an emission, sometimes without this association, but always commencing with flexion of the ring and little fingers of the right hand. Once or twice the fits had been arrested by some one forcibly preventing the flexion of the fingers.

Palmar fascia contraction affecting the ring and little fingers was ascertained to exist in the right hand, as also a well-marked phimosis.

The contracted prepuce was slit up, and the contracted palmar fascia was forcibly stretched and ruptured, so that not only was the contraction rectified, but the palm of the hand felt quite soft and natural.

After the operation the patient had one well-marked epileptic fit, and then no more. At the operation the hand was bandaged to a splint so very tightly that the patient complained of the constriction as very painful and irksome. This may have caused the one fit. After the first night the splint was put on more lightly.

Epilepsy from peripheral irritation is not uncommon. The above case is evidently an example of this, whether the exciting cause was the palmar contraction or the phimosis.

Miller has seen a well-marked example of epileptic fits due to phimosis. After circum-

cision the fits ceased for a time, but returned. The operation had been performed by the thermo-cautery, which at the time was being used for everything (tracheotomy among the rest); marked contraction of the cicatrix occurred (as might have been expected), and paraphimosis resulted. He cut the constriction; the fits again ceased, and have never returned, so far as known.

The author states that he has never seen a case in which palmar fascia contraction was the cause of epilepsy before, but considers that the one recorded is an example.

#### A CASE OF PARALDEHYDE HABIT.

In the *Edinburgh Medical Journal*, ELKINS records such a case. After detailing it at length, he gives the following summary concerning it:

It will be noticed that many of the bodily and mental symptoms related above, with some notable exceptions, such as the extreme emaciation, the marked effect upon the heart's action, and the abnormally large appetite, are similar to those found in delirium tremens; and, from the chemical relationship of alcohol and paraldehyde, this is what one might expect.

Not knowing what might be the effect upon such a weak subject, after such long use, of suddenly stopping the drug, it was intended to diminish the dose gradually, but the patient's mental condition prevented this arrangement from being carried out. It is possible that the more acute mental condition after admission to the asylum may have been due to the sudden deprivation of the long-used hypnotic. It is doubtful, in the treatment, how much credit should be given to the sulphonal, for it may be that a crisis was just about to take place when the drug was prescribed.

There was great emaciation; anæmia; slight rise of temperature in the evenings.

The heart's action was weak and irregular; pulse intermittent and soft; palpitation.

Stomach derangement, especially flatulence; costiveness; bulimia.

Breath smelt of paraldehyde.

Motor symptoms: General muscular weakness; general tremulousness, especially in tongue, facial muscles, and hands; gait feeble and unsteady; general restlessness. Sensory symptoms: "Strange feelings" running through body. Mental symptoms: Insomnia; great mental anxiety and agitation; discontent; unreasonableness; mental confusion; mental excitement; temporary loss of memory and incoherence of speech; shouting; tendency to

strip himself; hallucinations of sight (he saw "strange beasts"); hallucinations of hearing (he heard his death would appear in to-morrow's paper; he heard his wife had said she wished he were dead); delusions (that he was being poisoned; that his milk was drugged with laudanum; that a woman was in his bed, preventing him from occupying it; that people were tormenting him; that the doctors meant to kill him; that the house was on fire; that harm was about to happen to him). It will be noticed that the hallucinations of sight and hearing and the delusions were all of an unpleasant kind.

The treatment lasted about three months.

#### *THERAPEUTIC VALUE OF SALOL IN CHOLERA DIARRHŒA.*

M. Molkowitsch (*Therapeutische Monatshefte*, September, 1893) writes of his experiences with salol in choleraic diarrhœa which he gained in Nioching-Novgorod, Russia, in the summer of 1892. He analyzes one hundred cases to show the length of time which elapses between the occurrence of diarrhœa and the appearance of general symptoms of cholera. Excepting in ten cases, in which the time was only from one and a half to six hours, the interval ranged from six hours to a few weeks. From this fact he assumes that ninety per cent. of the patients, with the greatest probability, could have been rescued if from the very first appearance of the diarrhœa they had received the necessary medical attention; that is to say, if the cholera bacilli in the bowel had been rendered harmless before they had had time to develop the peculiar poison to which the general symptoms of the disease are attributed.

Molkowitsch treated nearly two hundred cases of diarrhœa with salol. He does not assert that they were all choleraic, though he believes they nearly all were. The diarrhœa lasted from a few hours to several days, generally from one to three days. In these cases the stools at first were partly solid, but subsequently watery. In a certain number (about twenty per cent. of the whole number of cases) the evacuations were accompanied with vomiting. Some of the cases subsequently to the beginning of treatment showed symptoms of cholera-poisoning.

Salol was used in all cases. The first dose to adults was 30 grains, but old people and those of weak constitution received only 15 grains. The three following doses of 15 grains he usually gave every three hours, and the later ones every four or five hours. Often the first two to

four powders of 15 grains were given every two hours, but the following ones every four hours. In a word, in the first few days patients received about 8 grammes (2 drachms), and in exceptional cases 10 grammes (2½ drachms). If the diarrhœa ceased and the patients felt neither weakness and nausea nor abdominal pain, and were comfortable, the powders were given less frequently,—every four, then every six hours. Usually the evacuations became less frequent within the first twelve hours, and the stools improved in character. If the patient rejected the first powder, a second was given, followed by hot tea.

In addition to the salol medication, patients were usually kept in bed, warmly covered; for pain, hot applications were employed and hot tea with citron given.

With the exception of dizziness and roaring in the ears, he never observed disagreeable symptoms following the use of salol. He regards the fear of carbolic-acid poisoning from salol as unfounded.

If after his treatment the diarrhœa did not cease in two days, the only cause was a failure to carry out his instructions as to diet. He never was compelled to use morphine but once, and then to relieve pain.

#### *CURE OF PLEURITIS, ESPECIALLY VERY ACUTE PLEURITIS.*

DR. AUFRECHT (*Therapeutische Monatshefte*, September, 1893) thinks the good results obtained in recent years in the treatment of pleurisy depend in great part upon the use of salicylic acid, of which he first wrote in 1883. His subsequent experience strengthens his earlier recommendation. But salicylic acid, not salicylate of sodium, must be used. The salicylate is weaker and produces marked secondary effects. When the pure acid is given in wafers, patients must always be admonished to follow the dose with a copious draught of water, in order to prevent a disagreeable burning feeling in the stomach.

Aufrecht has adopted the following modification of his former method of giving the salicylic acid: If in the first eight days no diminution of the exudate occurs, do not conclude that the salicylic acid has proved useless, but stop it for a day or two, and then begin again the dose of 6 grammes (90 grains) a day, in divided doses of 1 gramme, and so continue the treatment for several days, with interruptions of a day or two. Aufrecht adds that he has repeatedly found the same method of administration successful in obstinate rheumatic fever.

The best results in the treatment of pleurisy are obtained in cases in which the effusion has rapidly developed and is extensive, and in which the salicylic-acid treatment has been instituted as early as possible.

The author discusses the mode of action of salicylic acid, but reaches no positive conclusions. It is not beneficial in all cases, particularly not in effusions secondary to tumors of the mediastinum and lung, carcinoma or tuberculosis of the pleura, and in effusions of long standing.

As soon as the salicylic-acid treatment proves ineffective, the fluid should be withdrawn by aspiration. Fever is not a contraindication to the operation; on the contrary, the earlier the operation is performed the sooner will the remainder of the exudate be absorbed. The patient should lie upon his back, and Aufrecht selects for the point of puncture the fourth or fifth intercostal space between the anterior and posterior axillary lines. After the operation, patients, without exception, according to their age, receive from  $\frac{1}{6}$  to  $\frac{1}{4}$  grain of morphine to allay the cough which ensues from expansion of the lungs. Subsequently a drachm of salicylic acid, on the average, is given daily for several days.

Fraentzel was the first to call attention to a group of cases in which the pleurisy sets in suddenly with violent chill, high fever, and extensive effusion, which rapidly becomes purulent. Such cases have died hitherto, but Aufrecht reports two which were saved by prompt resection of the ribs.

#### THE TREATMENT OF PNEUMONIA.

This constantly-recurring topic of the treatment of pneumonia shows how the profession feel that in this disease we are often disheartened by our results. In the *Boston Medical and Surgical Journal*, SHATTUCK points out that no method of aborting the disease which has yet been proposed has made good its claims. Pneumonia, like typhoid fever, may abort spontaneously, but we cannot make it do so. Still, it seems that the method of Petresco, of Bucharest, is worthy of trial. Since 1883 he has treated seven hundred and fifty-five cases of pneumonia with very large doses of digitalis from the time they first came under observation. He gives for two or three days a strong infusion, and claims to be able to cut early cases short and to influence very favorably more advanced cases. His mortality now is only 1.22 per cent. He gives from 1 to 2 drachms of the leaves daily, the equivalent of

one to two ounces of our tincture. In like manner we have had no distinctly curative treatment, though we are encouraged to hope that the injection of immune blood-serum may prove to be such after further trial. In short, our efforts are at present confined to promoting the comfort of the patient and conserving his forces in every way to enable him to outlive the self-limited disease. This in itself may be much.

For the better application of this general principle it will be more convenient to divide the disease into stages, remembering always that these divisions are arbitrary, and that nature does not seem to feel herself bound strictly to abide by them. Patients very rarely succumb to the stage of invasion or preliminary congestion of the lung with active implication of the pleura. The danger here is not of dying; it is rather of loss of strength, which may be sorely needed later. The indication, therefore, in the ordinary case is to relieve the pain, to put the patient to bed and freely open the bowels, just as the mariner prepares his ship for an impending hurricane. The severity of the pain and any known or ascertainable peculiarity of the patient will decide the character and amount of the means for its relief. In the early days, at least, there can be no question of the safety of morphine, which should be used freely and frequently, hypodermically. Restlessness and an excited nervous system call for morphine nearly as loudly as does pain. Dyspnoea in the average case is at this stage due far more to the pleuritic pain than to state of the lung. But now and then we see a case in which so much lung-tissue is so rapidly invaded that the heart finds it difficult to adjust itself to the changed condition, and greatly oppressed breathing results. In such a case nothing gives such prompt relief as venesection, the freedom of which is to be proportioned to the age and vigor of the patient and its effect on the symptoms. With the veratrum viride treatment of the Philadelphia school the author has no personal experience. If internal antipyretics are to be used at all in pneumonia, it is only during the first stage that they are admissible. Even the best of them is somewhat depressing to the heart.

During the prevalence of the old doctrine of the nature of pneumonia and of inflammation, treatment was naturally addressed to the diseased organ, and antiphlogistics were used externally and internally. We now recognize the fact—or believe it to be a fact—that the cause of death in the second stage is rarely asphyxia as a result of the amount of lung involved. The loss of function of a portion of

the lung plays in most cases a rôle which is quite subordinate to that of cardiac exhaustion, dependent probably on the influence of toxins on the innervation of the heart rather than on changes in the myocardium. That it is mainly a toxæmia which weakens the heart, and not simply the mechanically-increased resistance in the right chambers, seems to be proved by the great fall in the pulse, as well as the breathing, coincident with crisis, although the physical signs over the affected lung area may show no appreciable change.

It is, then, the maintenance of nerve-force which we must try to secure. This means the avoidance of every unnecessary fatigue and the administration of the largest amount of the most nutritious liquid food which can be digested, with free ventilation of the apartment. It seems that the poultice and the envelopment of the chest in cotton or wool are relics of the old pathology. The poultice is the worse, as its frequent change involves notable fatigue and its weight is not insignificant. The author warmly recommends plenty of fresh air and sunshine. Morphine should be used more freely in the second stage than is customary. Here it is not called for by pain so much as by restlessness, cough, and sleeplessness. In any given case we must try to estimate the proportion of danger from respiratory failure. The smaller this danger the more freely can we use morphine, which will do more good in resting the nervous system than harm in other ways; and even in cases where the danger of respiratory failure cannot be disregarded, but morphine is indicated on other grounds, the inhalation of oxygen enables us to give morphine when we might otherwise feel compelled to withhold it. The writer does not recommend oxygen treatment, having in a considerable experience seen only one case—that of a Harvard student—where it gave marked relief, and even here the patient's age should have insured recovery. Our experience with this gas is now sufficient to enable us to estimate its value better and to use it more intelligently than a few years ago. Physiologists kept it out of use longer than we should have allowed them to do, saying that the consumption of oxygen is no greater when the pure gas is inhaled than it is under ordinary conditions. Even if this is true of the well, it does not follow that it is also true of the sick. It is probable that to-day clinicians are agreed that oxygen may be useful when a sufficient amount of air to arterialize the blood is prevented from reaching the alveoli, a condition which is present in some cases of pneumonia, as the result of

excessive secretion in the bronchial tubes in combination with the lung consolidation. Cyanosis, therefore, is the best single indication for oxygen. In such cases it should be used early and as freely as the purse of the patient will allow. Unfortunately, it is still a very expensive remedy; but its usefulness is wider than would appear from the above. Shattuck has seen refreshment, quieter respiration, a fuller pulse, and diminished restlessness, perhaps sleep, follow oxygen, even where cyanosis was absent or slight. Perhaps the gas acts as an aid in the combustion of toxins, all compounds of unstable character. The other chief means of stimulating the flagging heart, as reflected in the pulse and the character of the sounds, are alcohol, strychnine, cocaine, digitalis, and other heart tonics. Alcohol should be mentioned as very useful when the indications for its employment are present. Strychnine has grown in favor of late years, and justly. It is best given hypodermically, and, in severe cases, to the limit of toleration,  $\frac{1}{10}$  to  $\frac{1}{20}$  grain every three or four hours. H. C. Wood speaks highly of cocaine as an adjuvant to strychnine.

All writers advise and all practitioners use digitalis or one of its congeners, if there are any indications of a failing heart. The writer has used it constantly, but the rationale of its usefulness is not clear as it is ordinarily given. Perhaps we do not use it in large enough doses. It should probably be used hypodermically more than we do. He has seen this year prompt and distinct effect in several cases follow hypodermics of 30 minims of the tincture. Petresco's results are confirmatory of the idea that our doses of digitalis are often insufficient.

With the cold bath and cold wet pack, as remedies against high fever, delirium, and other nervous symptoms, the author has but slight personal acquaintance. A period of the disease which we all recognize as one of much danger in some cases is that immediately following the crisis. Exhaustion or collapse at this time calls for rapid stimulation; alcohol and ammonia internally, heat to the surface, brandy and ether under the skin.

In cases terminating by lysis, and in delayed resolution, a supporting treatment is to be carried out, according to the indications presented by the case in hand. The frequency of empyema as a sequel to pneumonia is never to be forgotten, if for no other than a therapeutic reason.

Lépine has recently employed with success injections into the thighs or arms of oil of tur-

pentine, when he feared that gray was passing over into yellow hepatization. Fochier first suggested and practised this method in puerperal septicæmia, having noticed that improvement took place when a focus of pus was established. The turpentine produces an abscess,—“of fixation,” Fochier terms it,—which can be opened later. Dieulafoy and Bard have each practised this method in pneumonia, with recovery in both cases. Others in France have also used it a few times.

In three desperate cases in the author's service at the Massachusetts Hospital, last winter, he had turpentine injected, in one case on the ninth, in two on the seventh day of the disease. All three died, as seemed certain they would, whatever was done or not done.

For therapeutic purposes, cases of pneumonia may be divided into three classes: first in frequency are those cases which will recover under any treatment or no treatment, unless they are grossly mismanaged; second, those which will die in spite of any and all treatment known at present; third, those in which judicious treatment may turn the scale.

Our object is constantly to strive to enlarge the third class at the expense of the second. Thus far our efforts have been unsuccessful enough. One method of curative treatment has been recently introduced which can claim an encouraging though limited success in practice, as well as foundation in analogy,—with tetanus, for instance. Only one case has been reported thus treated in this country, but it would seem our duty to lose no further time, and Shattuck proposes to test the method in his wards next autumn and winter.

He refers to the injection of blood-serum from a human being who has recently passed the crisis of pneumonia, or blood-serum or fluid derived from animals rendered immune to experimental pneumonia by the injection of pneumococcus cultures. The purpose in this method is to induce the crisis artificially, and that of thirty-nine cases thus treated all save one recovered. Whether the pneumotoxin and antipneumotoxin theory of its mode of action is final or not, remains to be seen. In the sole American case defibrinated blood was used, with results which do not encourage a second trial.

#### SALOL AS AN INTESTINAL ANTISEPTIC.

In the *Practitioner*, SYMPSON publishes a useful paper on salol as an intestinal antiseptic. He recalls the well-known fact that, after having been swallowed and passed through the stomach

unchanged, it is split up in the duodenum by the pancreatic juice into its constituents, salicylic acid and carbolic acid. Their action will be alluded to more in detail later on, but it may here be said that they are thrown out of the body partly by the kidneys (the urine not infrequently being blackened by the carbolic acid) and partly by the intestinal tract in the fæces. From experiments on dogs whose pancreases have been extirpated, there seems to be reason to think that salol can be absorbed from the intestine without the intervention of the pancreatic juice. As to its action on digestion, there are different opinions, some authorities saying that it unsettles the digestive processes and that it actually sets up gastric trouble. These statements refer to its action in typhoid fever, which will be mentioned presently; other observers have, however, noted directly the contrary results. Sympson has personally taken salol in 5-grain doses three or four times a day, both before and after meals, when he has been perfectly well, without experiencing the slightest interference with digestion or appetite. The following experiments will show, however, that salol does appreciably affect the different digestive ferments so far as regards their rate of action:

*Experiment 1.*—Ten grains of arrow-root were boiled in two ounces of distilled water, cooled down to 100° F., and ten minims of Bleasdale's pancreatic essence added. The solution became perfectly clear. When one grain of salol was added before boiling, the starch required twice the amount of pancreatic essence and an hour's more time (being kept at the same temperature) before the conversion was complete. If the salol was merely added with the essence, it made no difference. The same results followed, only less marked, from the use of half a grain of salol.

*Experiment 2.*—Five grains of boiled and finely-chopped-up white of egg were pounded up with the following mixture: Benger's liquor pepticus twenty minims, dilute hydrochloric acid ten minims, and two ounces of distilled water. For four hours this mixture was kept at a temperature of 100° F. The albumin had entirely disappeared and the mixture gave evidence of containing peptones. The addition of half a grain of salol checked the process considerably; at the end of the same time there were several fragments of egg undissolved, and two or more hours were required for complete dissolution. Both these sets of experiments were frequently repeated, and the results were distinct and constant.

Before finishing this brief account of salol, it

may be said that it has been accused of producing herpes and of increasing the delirium which frequently occurs in the course of typhoid fever. Sympson has not noticed this latter himself in either complaint or when he used salol in cystitis.

In normal digestion the semi-digested acid chyme is poured out from the pylorus into the small intestine, to be exposed to the influence of the bile and pancreatic juice. These complete the digestion of the various food-stuffs, and some of the products of this digestion are due to the micro-organisms which are present in the intestine. Their work seems to be modified or kept in check by the presence of bile, for, as Foster remarks, "Bile possesses some antiseptic qualities. Out of the body its presence hinders various putrefactive processes; and when it is prevented from flowing into the alimentary canal, the contents of the intestine undergo changes different from those which take place under normal conditions, and leading to the appearance of various products, especially of ill-smelling gases."

The stomach undoubtedly is responsible for some cases of dyspepsia where the chyme is passed on to the intestines in an imperfectly-prepared manner, which produces duodenal disorder. But in the following class of cases there is evidence that occasionally the secretions poured into the intestine are at fault. The patient is probably of a "bilious" temperament; he may have a clean tongue, with great loss of appetite, and consequent loss of flesh; no pain during a meal, but coming on about two and a half to three hours after. Very likely he is constipated, and when his bowels are relaxed the motion is grayish white. As a rule, he will not suffer from nausea, only a little retching sometimes, and instead of the gas being acid, as it so often is, it may be quite alkaline and "soapy," as a patient once told me. The seat of pain is the lower part of the abdomen, and is relieved by passing wind. There will, perhaps, be a slight yellowness, hardly amounting to actual jaundice. These cases belong to the same class as those described by Dr. Allchin in his lectures on duodenal indigestion. Sympson believes that the symptoms are due to excessive and faulty fermentation in the small intestine, owing to alteration in character and amount of the ordinary digestive fluids, and more particularly of the bile. Dilute nitro-hydrochloric acid to these patients, sometimes combined with liquor pepticus, to help the stomach do its work, has made little or no difference in their condition, and opium in any form by the mouth has not

given that speedy relief which it does in gastric affections. So, latterly, the writer has been in the habit of beginning with 4 or 5 grains of calomel, and following it in an hour or two's time with 10-grain doses of salol every four hours. This, to use the language of a somewhat enthusiastic patient, "acts like a charm" when taken about one and a half hours after meals. The pain ceases, the swelling of the abdomen does not appear, the appetite improves, and, more important still, the wasting—probably due to the non-digestion of a large part of the food—departs.

Salol has also been found exceedingly useful in a form of infective diarrhoea. Some months back the writer saw a family in a village near Lincoln who all had diarrhoea, passing dark-brown watery stools five, six, seven, or eight times in the twenty-four hours, attended with severe abdominal pain. In a few days several of the inhabitants of the village were seized with the same complaint, and every one had been into the first-mentioned house. Several more got it from the second source of infection. The probable origin of the disease was not ascertained. Opium alone in some of the cases was tried, but its action was far inferior to that of salol, whether combined with opiates or not.

In cases of ordinary diarrhoea, too, there are few remedies which more speedily check the flow and the pain than 10-grain doses of salol. Some years ago, in the *Lancet*, Sympson advocated giving glycerin of borax in the diarrhoea of infants, believing that undue fermentation in the intestines was the *fons et origo mali*. It does answer well, but salol is to be preferred in the severer cases, in doses proportionate to the age, as it is a little more certain, more antiseptic, and almost as agreeable to take.

Lastly, he has been using salol exclusively in typhoid fever, not so much on the idea of combating the specific poison, but of cleaning and keeping clean the intestinal tract, and so subduing the irritation of the glands of Peyer's patches and other ulcers there, and that caused by the secretion from these ulcers in the intestine. Salol also prevents the excessive formation of wind, which is sometimes so vexatious a trouble to the patient. Salol brings the temperature down generally one or two degrees, causes abundant perspiration (this can be readily combated by giving oxide of zinc, tincture of belladonna, and some quinine in a mixture), reduces the number of stools from twelve to fourteen in the twenty-four hours to three or four, and, when they are offensive, deprives them of any odor whatever. No bad effects

were noticed with regard to its action in producing delirium. Its use was continued in typhoid fever for about a week after the disappearance of diarrhoea. It was always given in ro-grain doses, suspended by means of compound tragacanth powder, at first (in typhoid fever and other complaints) every four hours, then every six, and for the last week three times a day. It was always given after food.

#### PROPHYLAXIS AND TREATMENT OF DIPHTHERIA.

ROBINSON contributes to the *New York Medical Journal* a long paper on this subject, of which the following relates to the treatment of the disease. He thinks that, despite the advances made during the past few years in our knowledge of the pathogeny of diphtheria, as is shown especially in bacteriological investigations of this disease, the treatment of it is still uncertain and unsatisfactory. The really bad, malignant cases frequently progress inevitably to a fatal termination, and in some of them it is doubtful if any treatment thus far tried will arrest their march for a while or ultimately cure them. Such appears to be the testimony of some excellent observers of wide experience. These fatal cases doubtless become so by reason of the toxic character of the epidemic and the extreme susceptibility of some patients to the virulent poison of the disease. It is generally admitted, however, that those patients continue to react most favorably who are actively and judiciously treated from the inception of the disease. The mode of treatment seems to vary considerably with different observers. There is, however, a tolerably large and increasing number of eminent practitioners who evidently consider proper local treatment of the highest importance. Of these, many use drugs internally, with the conviction of being helpful to the patients.

Among them may be cited Jacobi, who thus speaks of the use of bichloride of mercury when it is given internally: "That its beneficial effect is not at all limited to the cases of laryngeal stenosis, but also those of sepsis. Indeed, in a great many such cases it has been administered and found effective." On the other hand, Osler writes, that "we are still without a remedy capable of combating in any way the effects of the poisonous toxalbumins." Robinson did not see from bichloride of mercury "the specially good effect which many writers describe." The latest report, moreover, of one of the large German hospitals is to the effect that no internal treatment was employed, and the results

obtained with severe cases of diphtheria have been quite favorable as compared with numerous antecedent or contemporaneous results accomplished elsewhere. The report just referred to is that of the Friedrichshain Hospital in Berlin, where it is stated that "during the last two years no drug treatment was instituted," and yet there were sixty-four per cent. of cures. This experience is also corroborated by that at the Willard Parker Hospital, where, according to Dr. William H. Park, "the only constitutional treatment is to give alcoholic stimulants throughout the course of the disease to those showing any tendency to heart-failure." The great difficulty in obtaining the best effects of local treatment is due to our inability to reach directly all the parts involved with topical applications. Ordinarily it is believed that these applications should be distinctively antiseptic in nature. In regard to the particular drug employed, the strength, manner, and frequency of its use, there are great differences of opinion. Of course, the manner in which treatment is conducted must differ somewhat with adults and children, the latter being less amenable to reason and less willing, therefore, to submit quietly to the necessary manipulations for the cure of the disease. Most observers are united in the belief that our main efforts should be directed towards destroying or lessening the vitality of the bacilli, diminishing the local spread of the disease, neutralizing the toxic results of absorption of the poisons produced by the bacilli, and support of the patient's strength with food and alcoholic stimulants. Inasmuch as the majority of cases of diphtheria occur among children, we must first consider how such cases may best be treated. This will depend upon whether the disease affects the nose, the pharynx, the larynx, or all these organs. If it attacks the pharynx, and as soon as we have the first local evidence of this implantation, mild cleansing, disinfectant solutions should frequently be employed. Depending upon the age of the child and its degree of weakness or strength, the throat must be treated with sprays, with irrigation, or with gargles. Sometimes one, sometimes the other method is most successful, according to the age and willingness of the little patient. In this connection the fact should be emphasized that it is more useful and satisfactory to disinfect and cleanse the throat by means of sprays, employed not directly through the mouth, but indirectly through the nose. In this manner nearly every portion of the diseased membrane is brought into more complete contact with the medicated solution than in any other way, and with less distress

and fatigue to the sick child. Whenever the spray fills the nasal passages, it will almost inevitably, in the large number of instances, reach almost the entire naso-pharynx, the middle pharynx, and portions at least of the fauces and tonsils. Through efforts of gagging or choking by the patient, the latter parts are surely cleansed and disinfected. Nasal sprays should be rather coarse, never very strong, and should be repeated every hour or two. The frequency of their use should depend somewhat upon the malignancy of the case, the thoroughness with which they are employed, and the time of day or night. In this relation the author and Dr. C. A. Siegfried are in accord. The latter writes, "In the very young, sprays can be introduced through the nostrils to the back of the throat;" and the treatment of the Willard Parker Hospital is the same, where "all patients have their nostrils syringed with a bichloride solution." Dr. A. Jacobi also states, with his very large experience to guide him, as follows: "Gentle nasal injections reach the important part of the pharynx better than injections in the oral cavity." "Nasal injections must be made early, frequently, and persistently." In speaking of nasal and naso-pharyngeal diphtheria infection, Dr. Jacobi affirms emphatically that "nasal injections alone are beneficial, and sometimes so to a remarkable degree." Immediately after the use of the spray, a strong disinfecting solution should be applied directly to the diphtheritic patches in the throat by means of a swab or brush. The sprays for the nose must be preferably made from mild solutions of carbolic acid with lime-water, borax, or bicarbonate of sodium, or else from very dilute solutions of bichloride of mercury. The solutions of carbolic acid should not be stronger than one or two per cent.; those of mercury, 1 to 4000, 8000, or 10,000.

In this connection should be mentioned that the *résumé* of the collective investigation of the THERAPEUTIC GAZETTE (1883) is not favorable to the use of carbolic acid. It is regarded as a useless and positively harmful application. Jacobi seems to support this view, despite the fact cited by him that Prudden found that a one-sixth-per-cent. solution suffices to stop the emigration or leucocytes.

From time to time, or about once every four hours, it is wise to give the fauces, tonsils, and pharynx a thorough, direct cleansing with this same spray or by means of a syringe. The local applications with a brush or swab to the back of the throat should be made with a solution of bichloride of mercury (1 to 500, or even 1 to

250). During these necessary manipulations the child should remain in bed or be held on the lap of the nurse, and wrapped in a blanket. Dr. Billington thus describes how nasal syringing can best be accomplished: "The assistance of two persons is required. The child is seated across the lap of one of these persons, who secures his hands with one of her own, and with the other holds the basin to receive the discharge. The other person stands behind the child, takes his head between the palms of her hands, and, leaning forward, holds it firmly against her breast. A third person, who should, when possible, be a physician, can then easily make the injection into the child's nostrils without the danger of injury to them by its sudden movements." To show how opposed is the experience of competent observers may be cited Jacobi's judgment, which is that "it is acknowledged as a positive rule among all good practitioners that no child must be taken out of bed for the purpose of injections, that the preparations for the procedure must be made out of sight, and the injections given quickly but gently, in a recumbent or semi-recumbent posture." Subsequent to the cleansing and swabbing, the child should be allowed to rest during a half-hour or an hour. Then a dose of the tincture of the sesquichloride of iron in glycerin and water, or a tablet of bichloride of mercury in solution in water or milk, should be given, followed by liquid food and alcoholic stimulant. The amount of the tincture of iron given should be from 1 to 2 drops for every year of the child's age; that of mercury, in tablet form, from  $\frac{1}{100}$  to  $\frac{1}{50}$  grain. The best old brandy, in amount proportionate to the age and condition of asthenia, should be given in milk, alternated occasionally with beef-juice or concentrated broths of mutton or chicken. Meanwhile, of course, the antiseptic vapors (referred to under prophylaxis) of turpentine, carbolic acid, and oil of eucalyptus should be kept in use more or less constantly. They must also be directed in such a way from a croup-kettle under a hood over the child's head, or a tent around the crib, with suitable supports and an opening for ventilation, as to allow the child to inhale the vapors sufficiently to obtain an appreciable medicinal effect in this manner.

Robinson's method is based upon a judicial estimate of the conditions involved, and with due regard for the knowledge thus far acquired through experimental research and clinical experience. There are many other agents, as we all know, in the nature of caustics, astringents, disinfectants, dyes, solvents, etc., which have been praised by different observers for their

curative action in diphtheria. Among them all, none seems to merit confidence as much as those already mentioned, especially when they are employed after the manner indicated. Many practitioners laud their use more than they do other agents of a similar or different order. Personally, the author believes that freshly-powdered cubeb has a very marked action in changing favorably the character of the membranous deposit and in lessening the accompanying catarrhal inflammation of the fauces, which always is allied with the evident diphtheritic manifestations.

To make applications more frequently to the nasal passages or to the throat than the writer advises is unnecessary and often injurious. They frighten and exhaust the child too much. They do not allow it to take and retain sufficient nutriment. If the solutions are made stronger, they are too irritating to be frequently repeated, and perhaps render the mucous membrane of the parts affected more prone to become involved by the encroachment of the disease than they otherwise would be. The failure to cleanse the nose and naso-pharynx efficiently is one reason why an otherwise good method of treatment is not oftener followed by the amelioration or recovery of the patient. The cleansing of the nasal passage is carried out whenever the presence of diphtheritic membrane in this organ is assured. In cases, however, in which this membrane is not apparent it is too often neglected. Absorption of many poisonous products is thus frequently permitted when it might be in part prevented. Many cases, no doubt, become much more serious through the omission referred to. Is it not true that absorption from the nasal passages takes place more readily than from the fauces? Do not the most serious cases usually show extension, sooner or later, of the diphtheritic process to these passages? Why not, therefore, avoid or prevent this grave development, if possible, by rational means? In regard to the frequency of local applications, it is again urged very strongly not to employ them more frequently than above advised. Meddlesome or too much interference is ultimately injurious in diphtheria, and mainly because it exhausts vitality and prevents essential recuperation by means of rest, food, and stimulants. Applications of undue strength frequently made to the nasal passages occasion pain and irritation, which increase notably the distress of the patient, with no compensating return, and make the membrane, by possible abrasions, more susceptible to the virulence of the disease. Whenever the symptoms point, unfortunately, towards

the involvement of the larynx, we should rely far less upon the utility of disinfecting sprays than in nasal or pharyngeal diphtheria, inasmuch as they penetrate very little, if at all, within this organ. Antiseptic vapors, the internal use of the medicines which have a favorable constitutional effect, are here more to be trusted. In the event of considerable laryngeal obstruction, we must make use of vomiting agents,—such as turpeth mineral, alum, ipecac,—if the child's strength permits, and follow their use with active stimulation. Occasionally false membranes from the larynx are thrown off by this means, and great temporary relief is obtained. At times no remedial effect is produced, and the child is only weakened and distressed to no purpose, for the laryngeal obstruction after their use is quite as great as previously. Under these circumstances we must look to intubation or tracheotomy as our sole remaining means of help.

In support of his views, Dr. Robinson quotes the following: "At a meeting of the Michigan Medical Society the secretary demonstrated, in a tabulated statement, accompanied with a graphic chart, important facts in the various outbreaks reported by local health officers during the year 1886. In 102 outbreaks, in which there was neglect of one or both of these measures, the average number of cases to the outbreak was a little over 16 and the average number of deaths 3.23, while in 116 outbreaks in which both were enforced the average number of cases was 2.86 and that of deaths .66. In other words, these simple precautions reduced the number of cases occurring during the year by 1545 and the number of deaths by 298."

Finally, Dr. Robinson closes his article with the following from the last published paper of Dr. William H. Park. Dr. Park writes, "The making of a true diagnosis in every case is not of scientific interest only, but of great practical importance. Care for the public health requires that every case of possible diphtheria be properly isolated and treated as diphtheria until all doubt is removed. Regard for the patient demands that no suspicious case that is not diphtheria be regarded and treated as such any longer than the fourteen hours absolutely necessary for making the diagnosis. In doubtful cases, therefore, it is the duty of physicians to obtain a diagnosis by the use of cultures. A correct diagnosis will also be a satisfaction to them, and will be a help in prognosis and treatment, and of great value in the diagnosing of future cases. The efficiency, simplicity, and cheapness of the methods for making an early

48 THE ELECTRIC GAZETTE.

diagnosis in doubtful cases would seem to render its employment by health authorities among the poorer classes advisable."

#### INTRATYMPANIC OPERATIONS.

In a valuable paper in Buck's *Reference Hand-Book of the Medical Sciences*, September, 1893, DR. E. B. DENCH details the various measures which have had trial, generally brief and unsatisfactory, for the relief of middle-ear lesions. The present status of excision of the drum-head and ossicular chain, wholly or in part, is well presented, with the weight of this earnest worker in its behalf. His operations now number forty: eleven in non-suppurative cases, with great improvement in hearing in six and moderate gain in four. In the twenty-nine suppurative patients, hearing was often good, but was improved in eighteen and perhaps lowered in one. The discharge stopped completely in fifteen cases and lessened in nine, while five were still under treatment. The duration of observation is not stated; and while the writer regards his results as less good than he could wish, there is a chance that later study would further reduce his satisfaction, the additions from the category of "unhealed" being probably more than offset by relapses among those rated as cured. His quotation of other men's results is at times misleading, for nineteen of the forty-two cured cases of the seventy-five in Ludwig's report had a simultaneous trephining of the mastoid, without which they would doubtless have fallen among the failures, as did others later cured by this operation. The fact that Dr. Dench has been doing but a dozen or so excisions each year indicates that he selects his cases with more care than many of his colleagues. He gives a truer representation of the matter than some more extended series, where the operation was often a first rather than the last resort.

#### CATARACT EXTRACTION WITH THE IRIS RETRACTOR.

DR. FRANCIS VALK (*New York Medical Journal*, October 28, 1893) describes his method of operation as follows:

At the time when he is ready for the operation he instils a sufficient quantity of a solution of cocaine (four per cent.) to render the cornea anæsthetic, but not to dilate the pupil. The patient is then placed on a steady table or bed, with a good clear light on the eye, and the lids are opened with a speculum. The eye is then washed with a solution of boric acid, while his instruments are all placed in boiling water and

then on a clean towel and covered until wanted.

*Section.*—This he considers the most important part of the operation, as upon a good section, he believes, depends the ultimate success. This should be in the same plane, except at the finish. He wishes to avoid the conjunctival flap, and by the perfect coaptation of the wound in the cornea we may avoid slow healing, septic infection, and prolapse or incarceration of the iris. He makes the section either upward or downward, according to the eye to be operated upon, as upward in the right eye, downward in the left, or, if the operator is ambidextrous, then both sections may be made upward, as he considers the upward section preferable. He prefers, in making his section, to cut always towards himself, for in so doing a much smoother and clearer cut is produced. He always makes the puncture and counterpuncture wholly within the corneal tissue, through its transparent margin about one millimetre from its periphery, and so that the cutting edge of the knife will just cover the pupillary edge of the iris on the side towards which he proposes to make the section. If possible, he rapidly makes the section of the cornea with three distinct cuts: first, carrying the point of the knife, as soon as the counterpuncture is made, upward and forward, cutting one side of the cornea; then the heel of the blade is drawn upward and backward, so cutting the opposite side; then, turning the knife on its long axis, the section is completed with the third cut by pushing the knife steadily forward until released. He thinks De Wecker, of Paris, first suggested this method, and he prefers it to all others. As he completes the section in the above manner, the knife comes out some distance from the scleral junction, leaving room for the iris to be tucked in when drawn back by the retractor.

At this time prolapse of the iris may occur; if so, it must be returned with the spatula if we wish to save the iris; but if not, then it may be drawn out and cut off if we decide an iridectomy is best. Another complication that may occur at this stage, particularly in very old people, is the rupture of the capsule, or the zone of Zinn, with the presentation of the lens at the section; if so, it must be removed at once by pressure on the cornea. He is inclined to think that, should there be any tendency to prolapse at this stage, it is better to perform an iridectomy at once to prevent any future prolapse as the healing process proceeds. If no complications arise, he then proceeds to open the capsule by a peripheral incision, passing the

cystotome inward to the pupillary space, then under the iris, and sweep it around beneath the edge, so as to cut the capsule in more than one-third of its periphery on the same side that the section has been made.

The eye being now ready for the extraction of the lens, it is grasped by the fixation forceps, directly opposite the section, and held steady by a careful assistant. He now takes the retractor in the left hand, and, with the blades closed and the set-screw so arranged that the blades will open to about the diameter of the pupil, he insinuates the ends through the section to the pupillary space. The blades are now opened by pressure and the iris drawn back and tucked beneath the edge of the lower corneal section. Holding it steady in that position, a slight pressure is made on the opposite side of the cornea by a spoon or hook, causing the lens to rise up and easily pass out over the ends of the blades. As it does so, and as soon as the lens presents itself at the section, the retractor is pushed slightly inward, at once releasing the iris. The retractor is then generally removed, with the lens lying in the concavity of the blades. As the lens clears away, we find the iris back in its position, not injured in any way, nor has it been exposed to the air, as may occur in simple extraction.

In case there should be any cortex remaining, which he does not think will be absorbed or will interfere with the vision, he reintroduces the retractor, and, drawing back the iris again, these masses are easily pressed out with the spoon. This completes the operation, and, the section being in perfect apposition, the speculum is removed, the eye gently closed, and the bandage applied.

#### MASTOID TREPHINING AND THE SURGICAL ANATOMY OF THE TEMPORAL.

In a paper read before the Philadelphia County Medical Society, May 10, 1893, DR. B. A. RANDALL remarks upon fifty cases operated upon in his previous four years of practice, with the important claim that they were from among upward of two hundred cases in which the symptoms of mastoid disease had been threatening. Nearly three-fourths of the patients had been brought to resolution without operation, hot syringing and rapidly-changed fomentations, with *rest in bed*, being his principal reliance for the relief of pain and inflammation. But two cases of the fifty had been lost, only one with room for blaming the operation; and the cure in the remainder had generally been prompt and lasting. The utmost thoroughness

in removing all necrosing tissue, in the directions where this was safe, was claimed to be the true conservatism, but that the violence to the organ of hearing should be the minimum possible. Safety should never be sacrificed to brilliancy, and in the more precarious regions too little should be done rather than too much.

In the supplement of the *Reference Handbook* above referred to, the same writer gives a brief and summary view of mastoid anatomy, confirming decidedly the claim of those who insist that every operation should be done as though the bone was known to be of the most dangerous type. The lateral sinus, which generally approaches within some six millimetres of the surface at a point corresponding with the insertion of the auricle, and some twelve millimetres back of the meatus, may be much more anterior or superficial, leaving absolutely no room for trephining the bone, and this in any type of long or broad head and on either side, contrary to the claim of Koerner that it is generally much safer on the left and in the long, dolicocephalic skull. The middle cerebral fossa is also quite as variable, and may have its floor as low as the upper margin of the auditory meatus. It was never lower in the five hundred skulls measured; maximum or minimum height was found in every type of cranial form. Mastoid trephining should, therefore, be done only with an instrument permitting every stage of the penetration to be closely observed, as in chiselling; and the point of entrance should be as close as possible behind the spine, which can almost always be found marking the posterior margin of the auditory meatus. The surface should be closely inspected, after thorough baring, for any sign of a superficial sinus. The channel should lie close behind the canal, and not rise above its roof except as the antrum is approached. The inner wall of the antrum with the facial canal is probably never less than fifteen millimetres from the surface, so penetration to this depth in the prescribed direction can hardly reach the labyrinth or facial nerve. In children the antrum is more superficial the younger the child, and the sinus and cerebrum are absolutely as well as relatively less exposed to injury in a properly-executed operation.

#### INDIRECT MESSAGE OF THE LENS FOR THE ARTIFICIAL RIPENING OF CATARACT.

DR. EDWARD JACKSON (*New York Medical Journal*, October 28, 1893) describes his experience with Dr. Joseph A. White's method of

ripening immature cataract, a method suggested by Dr. T. R. Pooley, of New York. Seven cases are reported. The following is the method of operating:

After the full dilatation of the pupil and the free instillation of cocaine, the anterior chamber is tapped with a paracentesis needle or broad needle, the incision being kept open by the point of the needle until the aqueous has been completely withdrawn with some little pressure of the fingers through the lids upon the globe. He uses the fingers for fixation without a speculum. Then a tortoise-shell spatula is pressed upon the cornea within the area of the pupil and rubbed around in a circle and then in radiating lines, stroking from the centre towards the periphery of the cornea. During this latter manipulation the margin of the pupil will be seen to retreat before the spatula, so that a large part of the anterior surface of the lens can be acted on without pressure upon the iris. The manipulation is continued a minute and a half to two minutes and a half.

The *after-treatment* consists of closing the eye for a few hours and the subsequent instillation of a mydriatic until the eye is free from hyperæmia. The preliminary instillation of cocaine is repeated three or four times, using it more freely than he would for cataract extraction, with the idea of rendering the cornea more flexible.

To summarize his conclusions with reference to this method of ripening cataract:

It seems more certainly efficient than Förster's.

It is almost entirely free from danger.

It is probably a better means of avoiding prolonged practical blindness than the extraction of the immature cataract.

#### A DEPARTURE IN THE OPERATION OF CANTHOPLASTY.

DR. KENNETH SCOTT (*Ophthalmic Review*, 1890) writes as follows:

The usual classical operation of canthoplasty cannot always be relied on as an unfailing remedy in cases of blepharophimosis or blepharospasm. More particularly is it true in those cases where the condition is an extreme one, or where there is, or has been, a considerable amount of inflammatory action in the eyelids, accompanied by thickening and very often by hypertrophic degeneration of the palpebral conjunctiva. These are the cases in which the operation of canthoplasty is most often called for, and when the one which is usually de-

scribed has been performed there is often a slight reactionary cedema, the lips of the wound approximate, and in spite of every preventive effort a reunion of the opposing surfaces occurs. Sometimes, on the other hand, the middle suture, which is placed in the outer angle of the palpebral fissure, tears its way through the conjunctiva, and the eye returns again to the condition it was in before operation.

The following is the manner of procedure which he now invariably employs: The outer canthus is divided with scissors in the usual way; a spring eye-speculum is then introduced between the eyelids, and the portion of conjunctiva which is opposite the centre of the wound is freed by scissors from its attachment over the globe, almost as far as the corneal margin. The free edge of the conjunctival flap, still held in the fixation forceps, is attached by a fine silk suture, as in the usually described operation, to the apex of the skin wound, when it will be found that there is not the slightest tendency towards dragging. The speculum is removed, and the conjunctival edge is then sewed in turn to the opposing cut margins of the upper and lower eyelids. A silver-wire suture, which has been thoroughly softened in the flame of a spirit-lamp, is then passed right through the substance of the upper eyelid, from the skin to its conjunctival surface, near to its ciliary margin, and a short distance from the cut surface of the canthus. It is fastened by twisting lightly, so as to avoid constricting the tissues. The needle end of the suture is then passed through the substance of the eyebrow, directly over the outer third of the eyelid, and is fastened by twisting it there to the other free end brought up to meet it. The lower palpebral part of this strand of silver wire is then curved outward, with dissecting forceps, so as to evert the outer end of the new lid margin and prevent all possibility of its approximating to the opposing cut edge of the lower eyelid.

He has never known any suppuration or other irritation occur if the parts have been thoroughly cleansed previously with some efficient antiseptic lotion, and after operation an antiseptic dusting-powder, such as iodoform and boric acid in equal parts, applied.

The silver-wire suture should not be removed until it is seen that the wound between skin and conjunctiva is quite healed; this usually takes place about the fourth day. The operation can be performed with cocaine quite easily, except in the case of children, when a general anæsthetic is usually required.

THE THERAPEUTIC CONTRIBUTIONS OF  
OPHTHALMOLOGY TO GENERAL  
MEDICINE.

ARGYLL ROBERTSON, in an address delivered before the Ophthalmological Society of the United Kingdom at its first meeting in the session of 1893-94 (*British Medical Journal*, October 28, 1893), discusses the subject contained in the title. It is interesting to note, among other things, that he points out the advance which ophthalmology has made in the treatment of headaches, or in functional nervous disturbances so grave that they lead to the suspicion of serious cerebral lesion, which are yet remediable by suitable glasses and the performance of an operation on the muscles to overcome some latent tendency to misdirection of the eyes. The value of shortening the tendon is referred to, as well as advancement, the opinion being expressed that, although the general surgeon has long been accustomed to deal with muscular deformities by cutting through tendons, he is only now learning to deal with elongated and weakened muscles after the methods of ophthalmic surgeons.

The undoubted value of mercury in the treatment of syphilis is insisted upon, and the astonishing results by the use of this drug on syphilitic eye-affections, which may be watched with accuracy, is pointed out as proof of this assertion.

Local depletion, for example, in acute iritis, cyclitis, and even glaucoma, is commended, and general medical practitioners are urged to investigate its undoubted value in ophthalmology before giving it up in practice. In like manner, counter-irritation and blisters are commended, and the lesions presented to an ophthalmic surgeon are quoted as a therapeutic testing-ground for such medication. The following method of counter-irritation is the one employed in Edinburgh, and is most efficient, according to Robertson. It consists in moistening the upper lid and then rubbing a stick of lunar caustic three or four times across the moistened surface. Within a few minutes a burning pain is experienced in the lid, the skin becomes reddened and the lid oedematous, while the epidermis, at the point on which the caustic was applied, presents an ashy-gray tint. The severe pain lasts from half an hour to an hour, but the surface of the lid remains tender to the touch for two or three days. A black crust forms on the surface, but is cast off in six or eight days and leaves no permanent mark behind. The experiences of ophthalmic surgeons with nitrate of silver confirm a fact—now many times proved—that it ranks high among the various antiseptics.

THE EFFECT OF CORRECTING ERRORS  
OF REFRACTION IN EPILEPTICS.

The following abstract of a paper presented by DR. JOHN HERN to the Sixty-first Annual Meeting of the British Medical Association appears in the *British Medical Journal*, September 30, 1893:

Although it would be obviously incorrect to state that because an epileptic had an error of refraction it must be the cause of his epilepsy, yet it appeared probable that in some cases, at any rate, the eye-strain necessary in hypermetropes and others to focus a clear image on the retina might be the starting-point of the epileptic attack. At a meeting of the Ophthalmological Society early in 1893, Dr. Hern had shown the first case he had met with in which true epileptic seizures ceased on a correction of hypermetropia by glasses. In this case the patient had no "fit" if he used his glasses for reading, but if he neglected this an attack of true epilepsy occurred. Since then Dr. Hern had met with three other successful cases.

MR. HARTRIDGE thought that if the epilepsy were due to such a peripheral cause as might be produced by excessive or irregular action of the ciliary muscle, then the more completely this strain was relieved the greater the advantages which might be hoped to result.

MR. SYDNEY STEPHENSON urged the necessity of carefully distinguishing between the fits of idiopathic epilepsy and those resulting from hystero-epilepsy, because the fact would be generally admitted that the inception of any treatment novel to the patient would be likely to modify the fits associated with the latter condition. Again, assuming that peripheral eye-irritation would cause idiopathic epilepsy, it would be better to correct the ametropia as fully as possible instead of partially correcting it, as Dr. Hern had done in his cases. Finally, he suggested that further investigation was needed before a definite conclusion could be come to on the connection between errors of refraction and epilepsy.

BRIGADE SURGEON LIEUTENANT-COLONEL E. F. DRAKE-BROCKMAN mentioned two cases of lunatics who had cataracts, and in whom the cataracts were removed by operation. The effects on the mental conditions of these two patients were of the opposite nature. One, who before the operation was a mischievously mad girl, became quite docile after sight was restored. The other, who before the operation was a quiet and inoffensive lunatic, became very violent and had to be placed under restraint. Dr. Drake-Brockman thought that these cases might throw a side light upon the effect pro-

duced on the mental condition of patients by the restoration of sight or by its correction by suitable lenses.

DR. PERCIVAL had read the glowing accounts of some American ophthalmologists, who declared that they were able to cure many cases of epilepsy and insanity by correcting errors of refraction or by button-hole operations on the ocular muscles. A fair number of epileptic cases had been sent him, but he had no successes to report. No permanent diminution of fits seemed to have followed the most careful refractive correction. He would, therefore, think Dr. Hern's experience of three successful cases out of five most unusual.

MR. W. J. CANT said that he had seen one case in which the correction of hypermetropic astigmatism  $+2 + .75$  at 150 both eyes (full correction) apparently cured the epilepsy. The fits were not frequent—on an average once a week—and not severe. Many other cases of epilepsy had been examined and all the ametropic cases corrected, but only in one other case was there any relief to the fits.

#### IRRIGATION OF THE ANTERIOR CHAMBER AFTER CATARACT EXTRACTION.

HALTENHOF makes an abstract of Roethlisberger's thesis on this subject in the *Annales d'Oculistique*, September, 1893, as follows: After a complete study of the facts observed at Basel and in the papers published on this disputed subject, the author concludes in favor of irrigation as practised by Professor Schiess. The following are his conclusions: Irrigation of the anterior chamber aims only at the mechanical cleansing of the pupillary area and the reduction of the iris, but never has an antiseptic object. It is the quickest and gentlest process for extracting cortical remnants. The most suitable liquid is a lukewarm solution of concentrated boric acid, having the advantage over the physiological salt solution of remaining aseptic. Liquids which are not indifferent chemically—namely, solutions of chlorinated water, alcohol, sublimate, trichloride of iodine and distilled water—must be absolutely rejected, as they cause corneal troubles and iritic irritation.

#### ON THE ANTAGONISM OF ATROPINE AND MORPHINE.

DR. PRIESTLEY SMITH (*Ophthalmic Review*, July, 1893) abstracts an article by J. Samelsohn, reprinted from the *Centralbl. f. Klin. Medicin.*, 1893, No. 11, as follows:

The author points with surprise to the fact

that medical writers are still debating the question whether morphine acts as an antagonist to atropine. His own experience of the value of morphine in cases of atropine-poisoning has completely answered this question long ago.

During the course of twenty-six years Samelsohn met with nine cases of severe atropine-poisoning, and this represented a proportion of about 1 in 10,000 patients. It is somewhat surprising, in view of the very frequent use—and, as the author holds, the very frequent abuse—of atropine in ophthalmic practice, that serious toxic symptoms should occur so seldom.

Six of the nine cases were in children, and were mostly due to unskilful use of the remedy, the drops finding their way into the mouth instead of into the eyes. The amount of the poison entering the system could not be estimated in these cases. The toxic symptoms were those ordinarily produced,—viz., extreme excitement of the vascular system, great restlessness often passing on to delirium, and in some instances general convulsions. In every case a morphine injection promptly brought the alarming symptoms to an end. The remarkable toleration of atropine by the dog was well illustrated in one of these cases. The drop-bottle being overturned, its contents were licked up by a dog and produced in him no noticeable disturbance, whereas the small quantity of the same solution previously used for the child had produced severe toxic symptoms. Since adopting the practice of prescribing atropine for children only in the form of an ointment, Samelsohn has seen no further case of poisoning, even in the mildest degree. He adds, however, that the case in which a woman gave her child an ointment—happily not an atropine ointment—to eat has warned him that even this method is not absolutely free from risk.

The other three cases were in adults.

Atropine drops prescribed for a child were taken in mistake by the mother, in place of another solution which she had received for internal use. Being summoned to the patient, Samelsohn found the usual vascular disturbance and feeling of intense anxiety. A subcutaneous injection of morphine, .02 gramme (nearly  $\frac{1}{3}$  grain), quickly relieved the symptoms.

The next case was one of some diagnostic uncertainty. Being hurriedly asked, in the absence of the usual medical attendant, to see a patient suddenly taken ill, the author found a young man, twenty years of age, violently delirious, struggling with some friends who with difficulty held him in bed, gesticulating to drive

away the phantom figures around him; the face intensely red, the eyes brilliant, the pulse 140, the respiration 34, the pupils widely dilated. The state of the pupils suggested atropine-poisoning, but no member of the household was known to be using atropine in any form. It appeared that the patient had drunk, fifteen minutes before the onset of the attack, a home-made infusion for the relief of boils. A subcutaneous injection of morphine, of the same amount as the previous case, quieted the patient in a few minutes, so that he could himself give an account of the occurrence. It then transpired that the infusion drunk by the patient had been ordered by a dentist for washing out the mouth, and that the chief ingredient was belladonna leaves. Half an hour after the morphine injection the symptoms of poisoning began to reappear and soon again reached an alarming height. A second injection again removed the delirium and lowered the pulse- and respiration-rate. The improvement lasted three hours, when a third injection, followed by five hours' sleep, permanently removed all symptoms, with the exception of paralysis of the pupils and accommodation, which gradually disappeared during the following five days.

The final case is of especial interest, because the poison was given subcutaneously, like the antidote, and the dose was known in each case. A woman, aged fifty, under treatment in hospital, was ordered pilocarpine injections, and had received several such without any disturbance. Hurriedly summoned to her from an adjacent ward one evening, Samelsohn found her sitting up supported by the nurses, gasping for breath, the hand pressed to the heart, the face flushed and intensely anxious in expression, the pulse too rapid to be counted, the pupils widely dilated and fixed. The suspicion that the injection which an assistant had given a few minutes before was of atropine instead of pilocarpine was confirmed by a glance at the bottle still standing on the table. An immediate subcutaneous injection of morphine relieved the urgent symptoms in five minutes, removing the feeling of anxiety, reducing the pulse-rate, enabling the patient to lie down, and lessening the intense dryness of the throat; an ice-bag to the heart and the moderate administration of wine completed the relief. No further injection of morphine was needed, and three days later even the dilatation of the pupils had disappeared. The quantity of atropine injected was not less than .008 gramme (about  $\frac{1}{8}$  grain), that of morphine was .02 gramme (nearly  $\frac{1}{3}$  grain).

These observations show that morphine is a therapeutic antagonist to atropine; it appears to hold the toxic nerve disturbance in abeyance while the system eliminates the poison.

#### EXCISION OF A PIECE OF THE MUSCLE IN SQUINT OPERATIONS.

W. G. T. STOREY (*Ophthalmic Review*, July, 1893) abstracts an article by L. Müller, on excision of a piece of the muscle in squint operations, published in the *Monatsblätter für Augenheilkunde*, xxxi. p. 118, as follows:

The author believes that the operation to be described will be found an improvement on the ordinary operation of advancement. He prefaces his description of the operation with a very full account of the microscopic appearances in five pieces of antagonistic muscle removed by him (three from the rect. ext. and two from the rect. int.) compared with those of the normal muscle, specimens of which were procured from criminals. The chief points of difference were as follows in the antagonists: 1. The clear fibres (*hellen Fasern*) were to be found in relatively greater numbers. 2. In transverse sections the large number of nuclei in the muscle-cells and their central position in the cell was noticeable, and in longitudinal sections rows of nuclei were to be seen. 3. The finely-striated normal appearance of muscular tissue had largely disappeared, but fatty degeneration was not found, and the presence of connective-tissue degeneration was uncertain. Definite changes, therefore, were found, as was to be expected, in the antagonists, as these muscles are for a length of time overstretched.

Vieusse (*Recueil d'Ophthalmologie*, p. 330, 1875) first practised excision of a piece of the antagonistic muscle as a cure for squint, but he did this without combining with it tenotomy of the squinting muscle. Noyes also used the same procedure, both apparently in a few cases with good result, but the author's practice differs from theirs in the fact that he does not omit the tenotomy of the squinting muscle, but merely replaces the usual operation of advancement by one more consistent with surgical principles. He shows by quotations and by observations of his own that in the advancement operation the attachment of the muscle in its new position is difficult to secure, and may possibly, from its position being faulty, cause obliquity of the vertical axis of the eye. In his operation strict aseptis must be observed; the patient is put under an anæsthetic, to avoid the difficulties caused by spasm of the muscles. An incision is then made vertically about four m<sup>m</sup>

limetres from the limbus conjunctivæ, and the muscle freely exposed and caught on the strabismus-hook; its side attachments to Tenon's capsule are then divided with a pair of scissors by lateral incisions reaching rather farther back than the length of muscle to be excised; the length to be cut out is then measured with a pair of compasses, allowance being made to leave a piece one or two millimetres in length attached to the sclera; two strong silk threads are then passed through the muscle just behind the spot found by measurement, one above and one below, so as to include about one-quarter of the muscle each, and are made fast with surgical knots; one end of each suture is then cut off, so that there is left knotted into the muscle one thread above and one below; in front of these the muscle is now divided, and is divided again farther forward, so as to leave a stump one or two millimetres in length attached to the sclera; through this stump another pair of sutures is passed in a similar way, leaving two free ends; the two upper and the two lower threads are now firmly knotted together, and, if necessary, an ordinary Wölfler's tendon suture can be placed between them; the conjunctival wound is then closed with two sutures. The sutures in the muscle are never removed (in one of the author's cases they slowly, after two months, ulcerated out), and cause no inconvenience. Both eyes are bandaged for three days, and the sound eye is then half covered with a piece of plaster in such a manner that the patient can only see on that side on which the muscle has been sutured; on the fifth or sixth day the sound eye is altogether uncovered, and on the eighth day the eye operated on is also uncovered and the conjunctival sutures removed. The author gives a table of seven cases of strabismus divergens and seven of strabismus convergens thus operated on by him. His results seem to show that in strabismus divergens up to six millimetres a piece of muscle corresponding in size to the deviation, and in strabismus divergens greater than six millimetres a piece one or two millimetres greater than the deviation must be removed to effect a cure, and in strabismus convergens a piece about one millimetre shorter than the deviation. He gives a complete table of his results. Of the seven cases of strabismus convergens, four were completely corrected and three partially (to within one or two millimetres); the amount of squint before operation in the different cases was from five to ten millimetres. In the seven cases of strabismus divergens, three were completely and four partially (one to two millimetres) corrected; the amount

of squint before operation was from four millimetres to eight millimetres. The movements of the eye are not restricted after this operation as they are when the combined tenotomy is omitted, as by Vieusse and Noyes.

#### TENOTOMY.

PHELPS (*Boston Medical and Surgical Journal*, vol. cxxix. No. 28) after a discussion as to the comparative merits of tenotomy and replacement by force, and after a consideration of the value of manipulation and of braces in association with tenotomy, writes as follows concerning the operation:

Subcutaneous tenotomy should be performed upon all tissues which can be easily reached and divided with a knife without danger of cutting important blood-vessels or nerves. Nearly all of the tendons of the extremities can be subcutaneously cut with safety, and certainly one would never think of performing a large operation when a smaller one would do. When an open operation is performed, adhesions, sepsis, and wound infection are more likely to occur than in subcutaneous work.

There is, however, at the present time, but little danger from wound infection, and there is no objection to an open wound being made. It should be resorted to only where there is danger of cutting important blood-vessels, or for other reasons than to simply divide a tendon or nerves. The tendo Achillis should be divided subcutaneously.

Tendons passing through fibrous canals, as, for instance, those of the fingers, should not be operated upon in the fibrous sheaths, because adhesions usually follow.

The sterno-mastoid muscle should always be divided by an open incision along the clavicle. The iliacus internus and psoas muscles should always be divided at their attachment to the lesser trochanter by an open incision beginning at the greater trochanter and extending down the leg four inches. With a periostotome one can work over the femur, hugging it closely, and with safety detach the tendon from its attachment. The author did this once subcutaneously, and ligated the femoral about ten minutes after. The incision should be open to lengthen the biceps of the arm or split the tendon. Open incision should be performed when the hamstring tendons and surrounding tissues are shortened and require division.

The fasciculus given off from the tendon of the ring finger, when removed for the purpose of making the hand more useful for piano playing, requires an open wound. Open in-

cision, when performed on the sole of the foot for the relief of talipes varo-equinus, is not for the exclusive purpose of seeing just what is being cut, but to lengthen all the shortened tissues which hold the foot in the abnormal position.

Over-correction of any deformity should be practised. No tendons which are separated six inches can unite perfectly.

When open incision has been performed, after the required operation has been completed on the tendon, the wound should be closed and dressed antiseptically, and the parts should be kept at perfect rest for at least six weeks after the operation, after which, if deemed advisable, suitable braces can be applied.

By the introduction of strands of catgut, or tendons from the lower animals, reproduction of tendons may be made to occur.

#### *THE RADICAL TREATMENT OF CYSTOCELE OR PROLAPSE OF THE BLADDER AND UTERUS.*

CROWELL (*Medical Herald*, 1893) holds that cystocele usually follows parturition, and is due to faulty involution. There is, moreover, a condition of relaxation of the anterior wall of the vagina and of the floor of the pelvis permitting the descent of all relaxed superincumbent structures. The condition may be induced suddenly, but as a rule it is of slow development, so insidious in character that it becomes fully initiated before the patient is aware of it.

As a result of this prolapse, the bladder cannot expel its contents, hence there is residual urine, cystitis, pain, and tenesmus. For the relief of these conditions the slack in the anterior vaginal wall is gathered in, thus elevating the bladder to its normal position, and the uterus is anchored from above.

If a colporrhaphy is to be relied upon, it should consist in absolute separation and division of the vaginal septum from the bladder, removing such segments as are superfluous to the proper support of the prolapsed viscus. Such union should be stronger than those simply involving denudation, and better results might be anticipated; but, since the surfaces here involved are in an involuted, weak condition, any expectations of success from operations upon it alone must be doomed to disappointment in the majority of cases. To overcome the associated prolapse of the uterus the abdomen should be opened and the uterus sutured to the anterior abdominal walls at the lower angle of the wound. The technique now

employed consists in passing three silkworm-gut sutures through the fascia of the abdomen and the fundus of the uterus from side to side. Once the sutures are in place, the fundus is scarified and lowered and apposition made. The sutures are cut short.

Ventro-fixation, if practised before the expiration of the child-bearing period, might prove an embarrassment to a perfect rising of the uterus into the abdominal cavity during gestation. If such cases should present, as they have in the author's practice, the fixation may be effected by attaching the round ligaments by a suture passing through the fascia as previously described, then picking up the round ligaments of each side, approximating each to the other and both to the under surface of the abdominal wall. In this procedure the fundus of the uterus is in no way restricted. This latter operation serves every purpose for retro-displacements, or procidentia if not aggravated, but it is not sufficiently rigid in its anchorage to serve for the correction of any considerable degree of cystocele or vaginal prolapse.

#### *INGROWN TOE-NAIL AND ITS SURGICAL TREATMENT.*

HOWARD (*International Journal of Surgery*) claims that removal of the entire nail gives only temporary relief, and the trouble returns, usually tenfold worse; for when the nail grows out again it is thick and deformed, and often the distal end of the matrix destroyed and the nail more sharply incurved than before. Cotting, some years ago, suggested removing all the inflamed part by cutting away the whole side of the toe, treating the resulting wound antiseptically. The contraction of the cicatrix resulting from this wound draws the soft parts away from the nail. In performing the operation the first incision is made about three-sixteenths of an inch from the edge of the ingrowing nail, the point of the knife being carried directly towards the bone, but not deep enough to wound the periosteum. An elliptical wedge-shaped section of skin and subcutaneous tissue is removed. A piece three-eighths of an inch in width is often sufficient. The wound is closed with deep silk sutures. On the fourth day the sutures are removed and the wound dressed as in other cases. In from a week to ten days a shoe may be worn with perfect comfort. The operation is rendered nearly bloodless by wrapping a small rubber band about the toe; this is allowed to remain on until the wound is closed.

### *SURGICAL INTERVENTION IN A SEVERE CASE OF PELVIC NEURALGIA.*

RICHELOT (*American Journal of Obstetrics*) states that, in considering the utility of a radical operation for neuralgia, he refers to the most severe type of pain, situated in the uterus or appendages, corresponding to no discoverable lesion, and accompanied by a general neuro-pathic condition.

Laparotomy and vaginal hysterectomy are the two procedures to be considered. The former may be limited to a simple exploration, or include rupture of adhesions, partial resection of an ovary, unilateral castration, bilateral extirpation of ovaries and tubes. The latter may mean ablation of the uterus alone or of the appendages as well. Up to the present day laparotomy has been the only operation discussed. The author considers it far inferior to vaginal hysterectomy. He has himself performed the operation fifteen times in cases that had been partially cured by laparotomy, in five of which the neuralgia was the chief symptom. In all of them the result was good. Out of nine cases of hysterectomy not secondary to laparotomy, eight were successful. One of the patients no longer complains of pain, but has cardiac disease; two have been relieved of the pelvic pain, but complain of neuralgia elsewhere; five are perfectly well after a lapse of six, ten, and eleven months, and one after five years.

### *THE COLD DOUCHE AND TAXIS IN STRANGULATED HERNIA.*

RAIFORD (*American Medico-Surgical Bulletin*) claims that ninety per cent. of the cases of strangulated hernia can be reduced within a few minutes by the method of treatment which he describes. The operator should be seated to the left of his patient, and should perform taxis while an assistant pours, from a height, cold water over the tumor. With the index and middle fingers he first finds the constriction, the exact localization of which is materially aided by traction made upon the uppermost part of the tumor with the right hand. This should be done simultaneously with the palpation of the stricture and with the first application of the cold douche. The constriction found, the fingers are gently inserted beneath it, where they are held with a slight pull upward, while the tumor is lifted upward and pressed inward with the right hand, the cold douche being continuously applied. The author has in his cases placed the patient in the dorsal position, shoulders lowered, hip elevated, thighs

flexed at somewhat more than a right angle with the body.

Anæsthesia by inhalation or locally has never been found necessary, for reduction is accomplished in the time required to get the patient anæsthetized. In a few cases chloroform has been given, and a hypodermic injection of morphine or cocaine in two cases. ■

### *TRAUMATIC ATRESIA OF THE VAGINA, WITH HÆMATOKOLPOS AND HÆMATOMETRA.*

KELLY (*Journal of Surgery, Gynecology, and Obstetrics*) reports the case of a negress, about twenty-two years of age, who had been a constant sufferer since her first labor eight years previously, which was terminated by prolonged and severe instrumental interference. The child was still-born. Since that time she never menstruated, although suffering from monthly molimina, and with back-ache and discomfort in the lower abdomen. At one time she had an attack of pelvic peritonitis, during which she was confined to bed for several days. Upon attempting to make a vaginal examination, the finger passed into a large, smooth, capacious sac in which none of the ordinary landmarks were recognizable. Upon inspection to discover the source of error, it was found that the examining finger had entered the bladder without resistance through the urethra, which hung patulous under the pubic arch. Below this was a whitish spot composed of firm scar tissue about one centimetre in depth and one in breadth, representing the position of the vagina. Upon examining the pelvic organs bimanually by rectum and bladder, a series of large nodules were discovered in the posterior and upper part of the pelvis, which at first appeared to be myomata. A closer examination, however, showed these globules to be masses definitely arranged, one above the other, with shallow sulci between, and in the lower one fluctuation was distinctly felt. This was evidently due to distention of anatomical structures with preservation of their topographical relations. The upper portion of the vagina was distended with retained menstrual secretion; the cervical portion of the uterus had become converted into a sac, the internal os appearing as a constriction in the uterine body, while the upper portion of the uterus was likewise distended, thus forming the three masses, one above the other, in the following order: vagina, cervix, and uterine body.

No distention of the tubes could be distinguished. Repeated coitus through the

urethra had caused the enlargement of this channel. The patient was able to retain her urine about a half-hour.

With the index finger in the bladder and the thumb in the rectum, a large trocar was thrust between the thumb and finger, and evacuated five hundred cubic centimetres of thick, tarry blood. A dilator was introduced along the track made by the trocar, and the parts were widely torn asunder from one pubic ramus to the other. The canal thus made was four centimetres long. The edge of the vagina was now caught with forceps above the raw area and dissected free on all sides for about one centimetre, in the form of a collar, and, sliding down over the raw area, it was attached with six silkworm-gut sutures and a number of intermediate fine silk ones to the uninjured outlet. In this way the vaginal canal was restored without leaving any raw tissue. The result of the operation was a vagina of normal calibre and without apparent shortening.

#### THE SURGERY OF THE GALL-BLADDER.

BANKS (*Liverpool Medico-Chirurgical Journal*) has opened the gall-bladder on five occasions. The first two operations were performed upon elderly men, deeply jaundiced, and steadily becoming weaker and more emaciated. In each case a greatly-distended gall-bladder could be felt through the abdominal walls. This was stitched to the abdominal wall, and, when adhesion had taken place, opened. No stones were found in either case. The patients slowly sank from weakness, and after death it was found that there was cancerous disease present in both, involving the common bile duct. The third case was one exhibiting symptoms similar to those of the first two. He, too, had a greatly-distended gall-bladder. In this case the walls of the gall-bladder were so thin that, in attempting to introduce a needle through the peritoneal coat, bile oozed out through the needle hole. So it became necessary to slit up the bladder and allow the fluid to escape externally at once. Much of the jaundice disappeared, and the patient gained so rapidly in strength that he was soon able to get about again. A biliary fistula remained after the operation and refused to close. The man died some time later of cancer of the head of the pancreas.

The fourth case was that of a woman who had been jaundiced for some months.

At first there was only nausea, loss of appetite, and general malaise, but no pain. Some time later she had excessive pain in the region

of the gall-bladder, but no enlargement could be made out. The pain was so great at times that the woman had convulsions.

The gall-bladder in this case was found tucked up behind the liver at a great depth from the surface. It was small in size and contained only a little bile. It was strongly bound down by adhesions to the duodenum and neighboring small intestines. There was considerable difficulty in breaking loose these adhesions. Every touch produced fresh bleeding. On examination of the bladder a stone was found at its orifice. This stone was removed. It was impossible to suture the gall-bladder to the abdominal wound. To some parts of the gall-bladder wound it was possible to pull down the parietal peritoneum, the rest was closed with omentum. The patient made a good recovery.

The fifth case was a jaundiced female suffering from pain in the region of the gall-bladder. A distinct increase in the size of the organ could be made out by palpation. At the operation it was found to contain a stone, which was removed.

Robinson performed cholecystotomy on twenty-five cases not exhibiting jaundice, without a death, and considers the operation practically devoid of serious risk. He operated on nine cases where there was jaundice but no malignant disease, without a death.

With regard to cholecystectomy, he is distinctly opposed to it, except under certain rare circumstances; for instance, after cholecystotomy the cystic duct may be occluded, but the hepatic and common bile duct may remain free. Then a fistula remains, from which mucus but no bile exudes; in such a case he would remove the gall-bladder.

Cholelithotripsy he has practised on many occasions, chiefly for stones in the ducts; these he crushed with forceps protected with India-rubber, and pushed the fragments back into the gall-bladder. The calculi can be broken up with a needle previously. Sometimes, after crushing a stone in the ducts and pushing the fragments back into the bladder, he was content to leave the latter unopened.

He has collected seven cases of cholecystenterostomy, with one death. He recommends attaching the gall-bladder, not to the duodenum, which is fixed, but to the ileum, a few inches lower. A loop of the ileum is taken up and stripped of its contents; a ring of India-rubber is tied around the neck of the loop. This keeps it empty of both blood and chyme. Incisions are made into the bladder and bowel and the two structures are sutured together with

a Czerny-Lembert suture. The patient on whom he operated made a good recovery, and was well three years afterwards.

#### CATHETERIZATION OF THE URETERS.

KELLY (*Annals of Gynecology and Pediatrics*) describes an improved ureteral catheter, sound, and bougie, and refers to the methods of their use. Anæsthesia is unnecessary. The patient is placed in the lithotomy position, the bladder catheterized, and the urine set aside for comparison with that obtained from the ureters. The ureters are located by careful palpation through the anterior vaginal wall. The bladder is then distended with from five to seven ounces of aniline solution; this serves to do away with its rugosities, which would interfere with the catheterization. The catheter, closed at one end with a metal plug, is then introduced as far as the bladder, when its farther progress is assisted by sight and touch. The point is turned forward and the handle elevated, producing a slight prominence on the anterior vaginal wall, which forms a guide to the vesical orifice of the ureter. The end of the instrument is caused to glide in a fore-and-aft direction from the neck of the bladder to the cervix, in the median line, a little farther to one side, a little farther out, etc., until it reaches the ureteral eminence, which can be determined by the sense of touch. An attempt is then made to introduce the catheter into the ureter by carrying the handle to the opposite side, thus directing the point to the posterior wall of the pelvis; the instrument is then slightly withdrawn and turned a little more towards the side, and swept downward, outward, and backward in the direction of the ureteral prominence. The catheter is rotated with each of these motions until the point is directed fully outward and slightly upward.

When the catheter enters the ureter, touch will show that it holds a fixed position. It should be introduced into the ureter until its point reaches the wall of the pelvis, when the plug is removed from the end. A catheter may be introduced into the opposite ureter and both catheterized at one sitting. This is slightly more difficult. The urine from the catheter is caught in minim graduates. There should be a discharge of one-half cubic centimetre per minute from each catheter as a normal excretion.

The bladder being filled with aniline solution, the clear color of the fluid discharging from the catheters proves that it comes from the ureters. Fifteen minutes is an average

time for the duration of the catheterization. The urine of each side should be marked and set aside for examination. The catheters should be plugged and withdrawn, and the urine in each of them added to that in the graduates of the corresponding side.

#### DILATATION OF CERVIX FOR DYSMENORRŒA.

POND (*Annals of Gynecology and Pediatrics*) considers three classes of dysmenorrhœa according to the etiology.

1. Where the cervix is small and elastic.
2. Where the cervix is long, conical, non-elastic, and cartilaginous.
3. Where there are associated flexures.

In the first variety he recommends the use of a light Palmer dilator, one or more times, without anæsthesia. It should be carried to the full expansion of the blades, and applications made to the canal, or a strip of iodoform gauze introduced. This can be carried out at the office.

For the second condition he recommends the free division of the stricture on two or more sides, from the internal to the external os, with thorough dilatation, and the introduction of a stem to be worn ten to fourteen days or longer, if necessary. Following this the cervix should be dilated once or twice a month to avoid subsequent contraction. Very long cervixes require amputation.

In cases of flexion where, at times, it seems impossible to pass the light dilator, the Elliot repositr should be used, the organ carried into retroflexion, when the dilator can be easily passed beyond the angle of flexure. Should the cervix be dense, a heavier instrument may be used, and if this fail, incision and the stem are resorted to.

He reports seven cases illustrative of the application of the treatment in the different conditions, and suggests that dilatation be adapted to the relief of stenosis even in young girls.

#### CONTRACTION OF THE URETHRA IN WOMEN.

LOUBEAU (*Archives de Toxicologie et de Gynécologie*, 1893) refers to the rarity of this disease in the female. It is most frequently acquired, but may be congenital. When acquired, it is either of gonorrhœal or of traumatic origin. The gonorrhœal form is extremely rare. Cicatricial contractions may follow ulceration or traumatism. The symptoms are slow in appearing, owing to the dilatability of the canal.

The first symptom is a slight difficulty in micturition, which is followed by the sensation of a real obstacle, a lessened flow, pain in the back, groin, and pelvis. Cystitis may develop. Catheterization becomes painful or impossible. By vaginal touch the thickening of the urethra may sometimes be appreciated. The course of the affection is progressive. The diagnosis is established by the history and by an examination with a catheter. Inflammatory swelling of the urethral walls is to be excluded as well as spasm of the urethra.

A contraction of the canal may be produced by a polypus or tumor, but patient investigation will exclude them. Deviation of the urethra in cases of vesico-vaginal fistula may simulate obliteration. The treatment varies according to the case: cauterization, incision, electrolysis, dilatation, have all been resorted to. Loubeau reports a case of contraction due to cicatrization following cauterization for the removal of a polyp. The passage was almost entirely closed, but immersion in hot baths caused a flow of urine when all other methods had failed. Progressive dilatation was impossible, as no bougie or catheter could be introduced, hence internal urethrotomy was resorted to.

A narrow bistoury was introduced horizontally, following the normal direction of the urethra, and inserted to the depth of a little over an inch. The ensuing venous hemorrhage was copious, but easily controlled by compression. There was no post-operative incontinence of urine and not the slightest fever.

#### THE MANAGEMENT OF THE ABDOMINAL INCISION.

REED (*American Journal of Obstetrics*, September, 1893), in a paper read before the American Association of Obstetricians and Gynecologists, held in Detroit, June, 1893, referred to the occurrence of suppuration during convalescence, and the subsequent development of ventral hernia. These complications he refers to defective methods in the management of the abdominal incision.

These relate, first, to the preparation of the patient; second, to the formation of the incision; third, to the method of closure; fourth, to the remote or after-treatment of the wound. Defective methods of preparation depend chiefly upon failure to recognize and remove the debris and germ elements from the minute interstices of the integument.

Defective methods in making the incision relate chiefly to failure to recognize the linea

alba and to make the incision through it. Defective methods of closure relate chiefly to faulty principles in suturing. Defective methods of after-treatment relate chiefly to the application of the tight adhesive strap with pad, firmly compressing the incision. The methods recommended consist in a thorough cleansing of the abdomen by the application of, first, oil, next, ether with some strong alkali, cleansing with clear water, followed by the persistent application for over half an hour preceding the operation of a strong solution of bichloride of mercury. The incision should be made carefully in the median line and through the linea alba. The method of closure recommended is by interrupted suture of silkworm-gut, passed from within outward on both sides entirely through the tissues, but so passed that it enters the peritoneum near the margin of the wound, dips deeply into the median tissue, and is brought out through the integument near the wound margin. By this means all the structures are brought into immediate apposition when the sutures are tightened. They should not be tied tightly, and the knot should be on one or the other side of the incision.

The wound should be dressed with aristol or boracic acid, and a bandage carefully applied. When the sutures are removed a firmly-fitting adhesive strap should be applied, which does not exert such pressure as will induce compression of the incision with a subsequent tendency to separation of the internal margin. The advantages of the interrupted suture, as here suggested, consist, first, in the simplicity of application; second, in passing through and anchorage in the muscles; third, the apposition of like tissues to like tissues; fourth, painlessness after operation; fifth, minimum possibility of infection.

#### LAPARO-HYSTERECTOMY.

SENN (*American Journal of the Medical Sciences*, vol. cvi., No. 3), after a discussion of the indications and technique of laparo-hysterotomy, together with a report of two cases, submits the following conclusions:

1. Laparo-hysterectomy is justifiable when delivery through the normal passage is impossible without mutilation of the living child.

2. It is absolutely indicated where the conjugata vera is less than two and a half inches, when obstruction is due to fixed pelvic tumors and advanced malignant disease of the cervix.

3. Mutilating operations on a living child for the purpose of effecting delivery are no longer legitimate obstetric procedures, as laparo-hys-

terotomy and symphysiotomy are life-saving operations for both mother and child.

4. Hysterectomy after laparo-hysterotomy is only justifiable if the uterus itself is the seat of a life-threatening, removable disease.

5. Elastic constriction as a hæmostatic measure should not be resorted to in laparo-hysterotomy before the delivery of the child.

6. The uterine incision should be enlarged to the requisite extent by tearing for the purpose of diminishing hemorrhage.

7. The visceral wound should be closed by four rows of sutures applied in such a manner as to absolutely arrest the hemorrhage and completely separate the uterine from the peritoneal cavity.

8. Laparo-hysterotomy is also indicated in the operative treatment of single, large myofibroma of the uterus in young women when the tumor is located within or near the uterine cavity.

9. In such cases the uterine incision should be closed in the same manner as in operations on the pregnant uterus, and the bed of the tumor should be packed with iodoform gauze, which is brought through the cervix into the vagina, thus serving the double purpose of a hæmostatic tampon and capillary drain.

#### THE PRESENT STATUS OF THORACIC SURGERY.

GASTON (*Journal of the American Medical Association*, vol. xxi., No. 9), after discussing the various methods proposed, draws the following inferences:

1. All penetrating wounds of the thorax may be closed hermetically, by suture or otherwise, after allowing the discharge of fluid blood from the opening.

2. Foreign bodies lodged in the bronchi may be removed by incision of the trachea at the lowest available point.

3. Experiments on reaching the bronchi through the chest-wall afford little encouragement in undertaking operation upon the human subject.

4. Medication as a preventive and a curative agency in pleuritic effusion is worthy of trial before having recourse to aspiration.

5. Aspiration is indicated when there are large serous accumulations in the chest and likewise in pneumothorax, but cannot be relied upon for the relief of purulent collections.

6. Partial resections of ribs is attended with better results in some cases of empyema than the complete removal of the segments of several ribs.

7. The excision of a small portion of one rib with the introduction of drainage-tubes has been generally attended with good results.

8. Washing out the cavity of the chest is not requisite, except in contamination and decomposition of the contents.

9. The operation of thoracotomy for abscess and gangrene of the lung should be accompanied with antiseptic applications and with tamponage of gauze.

10. Tumors of the mediastinum may admit of interference, but further development of technique is necessary before the method can be generally advised.

#### ON A SIMPLE METHOD OF TREATING THE WOUND AFTER EXCISING HEMORRHOIDS.

JONES (*Provincial Medical Journal*, vol. xii., No. 140) recommends the following method of treating the wound after excision of hemorrhoids:

The hemorrhoid is placed within the clamp (Smith's by preference) and cut off, leaving about an eighth of an inch of pedicle. This cut edge is sewed with a catgut suture, the clamp removed, and the operation is complete. The best plan is to take a piece of catgut about eighteen inches long, with a needle at each end. One needle is passed through the upper end of the pedicle and a first knot is tied; then the needles are passed from left to right and right to left, and each time they cross the pedicle are tied. Except in the case of friable granular hemorrhoids, the cautery should not be used, as burning the pedicle of necessity means the subsequent separation of a slough.

#### DRAINAGE OF THE BLADDER BY MEANS OF AN OBLIQUE FISTULA AFTER SUPRAPUBIC CYSTOTOMY.

MARTIN (*Centralblatt für Chirurgie*, No. 47, 1893) advocates the method of oblique canalization, applied by Witzel, in the operation of gastrostomy, to drainage of the bladder after suprapubic section, and refers to one case contributed by Zweifel, in which a similar operation was performed after opening the peritoneal cavity for the extirpation of a carcinoma growing at the vesical orifice of the urethra. Martin operated on a man aged sixty-seven, suffering from retention of urine due to enlarged prostate. For seven years the patient had been compelled to use a catheter five times a day. Finally, he was not able to introduce the instrument, nor was the physician to whom

he applied any more successful. The bladder was distended so that it reached as far as the umbilicus. The prostate was markedly enlarged. It was found impossible to introduce an instrument by way of the urethra. The patient was put in the Trendelenberg position, and a three-inch incision was made, running down to the symphysis; the bladder was freely exposed; the peritoneal fold was found two inches above the symphysis and was easily pushed still farther upward by blunt dissection. The wound margins were drawn widely apart by means of retractors, and the whole anterior bladder-wall was exposed, so that the following manipulation was easily carried out: A trocar was thrust through the bladder-wall low down behind the symphysis, and a portion of black, blood-stained, offensive urine was withdrawn. The bladder-wall was fixed on each side of the canula by means of clamps; the opening through it was slightly enlarged by means of a bistoury, so that a Nélaton catheter of medium size could be passed through. This was secured to the bladder by means of a catgut suture, and then, by means of a series of sutures running at right angles to the long axis of the catheter, passing in and out of the bladder-wall to one side over the catheter and in and out on the opposite side, a canal was formed at the expense of the bladder-wall. This canal was two inches in length. The sutures were silk, and after they were tied they were reinforced by a continuous suture.

The wound was packed with iodoform gauze; the end of the catheter was brought out through its upper angle and was secured by means of an adhesive plaster. The healing of the wound was rapid, in spite of a severe venous hemorrhage, which recurred three times in twenty-four hours, but was stopped by means of ice and ergotine. This bleeding apparently came from wounds caused by violent attempts at catheterization. After three days the temperature was normal and the urine became clear and healthy in appearance. The urine escaped by means of a drainage-tube attached to the catheter. This instrument was changed on the twelfth day. On the introduction of a new instrument a very distinct elastic resistance was encountered. This was overcome by gentle pressure, and, the instrument entering, some urine flowed out. This resistance was evidently due to the reflex muscular contracture excited by instrumentation. After the fourth day the dressing was entirely dry. The fifteenth day after operation the patient was allowed to get out of bed. The end of a Nélaton catheter was fastened by means of a clamp and no urine flowed

by the side of the instrument. The capacity of the bladder rapidly increased, so that in a short time a pint could readily be retained without a drop escaping by the side of the catheter. The patient was perfectly comfortable, and four times a day released the clamp at the end of the catheter and evacuated the contents of his bladder.

---

*RHYTHMICAL TRACTION OF THE TONGUE  
AS A MEANS OF RESUSCITATING  
THE ASPHYXIATED.*

LABORDE (*La Tribune Médicale*, No. 46, 1893), who first called attention to the value of rhythmical traction of the tongue as a means of stimulating respiration, has collected much evidence in regard to the value of this method as applied to cases of threatened death from asphyxia. Among the cases contributed, that of Denuce is very interesting. The surgeon was performing a tracheotomy on a patient suffering from neoplasm of the larynx. Chloroform was being given; this had been preceded by an injection of morphine. Respiration was entirely suspended; the patient became blue and, indeed, almost black from asphyxia. Although a canula was placed in the trachea, there was no effort at breathing. Rhythmical traction of the tongue was at once made, and finally respiration was restored.

Massé states that this method is an excellent adjunct to the other well-known resources in case of accident during anæsthesia. By this means he has been able to restore dogs apparently dead from the administration of chloroform. Sometimes respirations were not renewed until after ten minutes.

Ménière, while operating for caries of the mastoid process, the patient being under the influence of chloroform, perceived that breathing had stopped, and on examination could not detect any motion of the heart. The face was cadaveric in appearance. The child was turned head down, artificial respiration was started at once, and the tongue was seized in a pair of forceps and rhythmical tractions were made upon it. The first respiration was not noted for six minutes. The child recovered.

Laborde holds that in chloroform anæsthesia, when death is threatened from respiratory or cardiac syncope, or the two combined, the tongue method is the most powerful and rapid means of resuscitation, aiding not only the freeing of the throat, but actually stimulating respiration. He contributes a case of apparent death from violent shock of an electric current. The strength of the latter was more than two

thousand volts. The hand of the patient was burned and the body was black. The tongue was seized with a pair of forceps and rhythmic traction was made upon it for more than an hour, at the end of which time natural respirations were resumed and the patient recovered.

#### THE TREATMENT OF ACTINOMYCOSIS BY IODIDE OF POTASSIUM.

NETTER (*La Tribune Médicale*, No. 46, 1893) presents a patient cured of actinomycosis by medical treatment. This patient was a woman, always healthy until last August, when she suffered from a left sero-fibrinous pleurisy. There was slight amelioration of symptoms under salicylate of sodium treatment. This was followed by an aggravation of symptoms without apparent reason. For some time there was found beneath the left breast a patch of hard œdema about as large as the palm of the hand. In the middle of this patch there appeared a nodule as large as a walnut. This was located over the anterior extremity of the twelfth rib. This nodule softened, and on incision there was evacuated a small quantity of pus. The rib was not denuded, but the opening did not close, and there was a long fistulous tract. Since the general condition became more serious, and inoculation of the pleuritic fluid on a guinea-pig gave negative results, actinomycosis was suggested, and a daily systematic examination of the discharge was instituted. This resulted in finding the characteristic filaments. These were not found in the expectoration, from which fact the author concluded that the disease was probably located in the posterior mediastinum, the pus having made its way along the ribs and having caused by inflammation of the contiguous structure the sero-fibrinous pleurisy. Iodide of potassium was administered. This was followed by prompt recovery. The author reports two other cases of pleurisy excited by actinomycosis. He states that this disease is rare in France. He states, further, that one hundred and eighty-five oxen suffering from this disease were treated in Chicago with iodide of potassium, and that seventy-one of them were cured. It is probable that the iodide does not act as a specific, since it has been shown that the organism will grow upon gelatin containing one per cent. of the drug. It perhaps acts by augmenting tissue resistance.

Six successful cases are reported from Holland. The drug must be given in full doses,—80 grains a day at first; diminished as the physiological effect is produced.

#### THE NON-OPERATIVE TREATMENT OF SALPINGO-OVARITIS.

SHOEMAKER (*Journal of Surgery, Gynecology, and Obstetrics*, August, 1893) refers to the value of the conservative treatment of inflammatory conditions of the tubes and ovaries. He believes that removal of the appendages should not be advised until other treatment known to be carefully applied has failed. As a guide to prognosis without operation, he mentions the amount of organized adhesions and to some extent the amount of prolapse of the ovaries. Should the appendages be badly adherent and prolapsed, relapses are frequent, and no definite progress towards a real cure can be made, though all soreness be removed by treatment and the patient's condition remain satisfactory. He counsels the removal of diseased organs, where there is no reason to expect pus, in a small proportion of the cases of salpingo-ovaritis. These are cases where adhesions are insurmountable, and there seems to be valid ground for considering the lesion present to be the starting-point of a stubborn relapse. A careful use of iodine, ichthyol, boro-glyceride tampons, and elastic wool packing is indicated before the decision is made. The operation will be decided upon much earlier in a poor patient than in a woman of leisure. Where the lesions are not so gross as to make the decision for operation imperative, there must be weighed against removal the risk to life, the possible destruction of the sexual desire, the liability to hernia, the persistence of adhesions of the bowel, bladder, or omentum to the stump or cicatrix, the flushings and paræsthesia which book themselves about the monthly molimen, even though there be no flow.

Palliative treatment has failed not only in those cases where the anatomical lesions are not considered great enough to call for operation, but also in a few instances of serious type where the patient or her family refuse operation. While the idea of permanent and absolute cure must be dismissed, the patient can be made comfortable. The treatment usually lasts several months, sometimes for two or three years.

#### ICHTHYOL IN ERYSIPELAS.

THOMAS (*Liverpool Medico-Chirurgical Journal*, July, 1893) refers to the treatment of erysipelas by ichthyol, and mentions four cases so treated, three of which were complicated by large surgical wounds. The onset of the disease was sudden and the temperature high. As a result of the treatment the disease was cured

on the fifth day. In only one case was there sleeplessness. None required stimulants, and all experienced great relief from pain after each application of the remedy. Success in this treatment depends upon a very thorough rubbing of a strong ointment of ichthyol with vaseline or lanoline into the red area and into the adjoining healthy skin, covering the parts with a sheet of lint or the ordinary surgical dressing.

*ABDOMINAL SECTION WITH ENTER-  
ORRHAPHY FOR GUNSHOT  
WOUNDS OF THE  
INTESTINES.*

BRADY (*International Journal of Surgery*, August, 1893) reports twenty-eight cases of gunshot wounds of the intestines operated upon by abdominal section at the Charity Hospital, New Orleans, with a total of nine recoveries. This does not include those cases of abdominal section in which the liver, spleen, or bladder alone was injured. No stress has been laid upon the existence of peritonitis, either plastic or purulent, previous to the operation, though this existed in about one-third of the cases operated upon, owing to the long time which had elapsed between the receipt of the injury and the operation. Of three wounds of the stomach, all died. Of three wounds of the colon, all recovered. Of thirteen wounds of the small intestines, six recovered. He believes that cleansing of the abdominal cavity is of the utmost importance and should be carried out with every care. This can be done by introducing a constant stream of sterilized water at a temperature of from 110° to 115° F. to the bottom of the cavity by means of a rubber tube of large calibre attached to a funnel. He objects to the use of absorbent cotton for sponging, as frequently this material has been detected in a post-mortem examination where cotton has been used during the operation. For suturing the bowel he uses silk.

As regards the nourishment after the operation, he thinks small quantities of liquid food administered at frequent intervals by rectum or mouth, according to the relative situation of the wound, would place the patient in better condition than where food is withheld for the first twenty-four hours. A wound of the stomach does not seem to preclude the administration of two ounces or more of predigested milk, together with half an ounce of brandy by the rectum, within twenty-four hours after the injury. Should a like wound of the colon be present, he gives the same food by the mouth, at equal intervals. These patients usually die of peri-

tonitis or exhaustion. The treatment of this is largely directed to maintaining strength until the violence of the attack has abated, so that by excessive caution in the administration of food the patient is handicapped in his fight for life.

*ISCHIO-PUBIOTOMY.*

HENDERSON (*Lancet*, August, 1893) reports the following case from notes of Pinard and Farabeuf. The patient, a thirty-two-year-old fivepara, was delivered at term of a living child by ischio-pubiotomy. She was delivered of her first child by version and basiotripsy upon the after-coming head. In her second labor she was attended by Pinard, who induced premature labor. The child was delivered by version, difficulty being met with in extracting the head. The child died in its fifth month. Her third child was delivered at term. After six ineffectual attempts with the forceps, version and an attempt at craniotomy, the seventh application of the forceps to the after-coming head, and finally traction upon the trunk, assisted by pressure upon the abdomen, her fourth child was delivered prematurely by forceps, child dying from prolapse of the cord. During her fifth pregnancy she consulted Pinard, and expressed the desire to give birth to a living child at all costs. It was first supposed that the child could be delivered by symphysiotomy. Repeated examinations, however, convinced him that there was ankylosis of the right sacro-iliac synchondrosis, and the operation of symphysiotomy was therefore inapplicable.

Pinard then consulted with Farabeuf, who calculated that if the margins of the obturator foramen of the ankylosed side were cut in two places as far from the mid-line as possible, the passage of a large head would be easy. The woman was, therefore, allowed to go to term. The operation was begun fourteen hours after the advent of labor. The ischio-pubic ramus and the horizontal ramus of the pubes on the ankylosed side were successively sawed through five centimetres from the median line. Tarnier's forceps was applied above the brim, and an infant weighing almost eight pounds was extracted without difficulty. The operation was simple, the only difficulty experienced being in passing the chain-saw around the horizontal ramus of the pubes. Hemorrhage was slight. The spontaneous separation after section of both rami amounted to two and six-tenths centimetres, and was increased four centimetres during the extraction. The soft parts alone were sutured. A bed-sore in the sacral

region was the only complication. Sutures were removed on the eighth day. Three days later the patient sat up, and on the thirty-second day she was able to walk and stand without difficulty.

#### TREATMENT OF SKIN CANCER.

In the discussion over Lassar's contribution upon this subject, read before the Berlin Medical Society (*Monatshefte für Praktische Dermatologie*, Bd. xvii., No. 10), KÖBNER held that the cases presented by Lassar were not conclusive, since Langenbeck had presented a similar favorable result from arsenic treatment, the patient, however, perishing a year later from recidivity. In Lassar's second case the diagnosis is not assured; in the third case the patient is not fully healed. Köbner holds that arsenic and all other remedies administered by the mouth are utterly without power, and that cure is never accomplished, excepting when the ulcer is completely removed by means of a knife in the early part of its course. Only when patients present themselves too late for operation should resort be had to medical treatment.

Bergmann gave the history of three cases in which ten, seven, and five years respectively had passed without recurrence. In considering the radical cure of skin cancer it must be remembered that cicatrization is followed by destruction of cancer cells. Such cicatrization may take place quite independently of any therapeutic treatment. Under some circumstances carcinoma will last twenty years and then undergo cicatrization. Small clusters of cells may remain latent for years. Following seborrhœa, ulcers develop which closely resemble carcinoma. Before a physician recommends internal treatment he should remember that these skin cancers frequently do not recur when thoroughly removed by the knife. Lassar, in answer to these criticisms, stated that he exhibited his patients simply to show that by arsenic treatment carcinomatous nodules in the face were prevented from running their customary course.

#### BLOODLESS AMPUTATION AT THE HIP-JOINT.

WYETH (*Medical News*, vol. lxiii., No. 24) describes at length his method of performing bloodless amputation of the hip-joint.

With the patient in the usual position for a hip-joint amputation, the limb should be emptied of blood, either by elevation of the foot

and lowering of the trunk, or by the Esmarch bandage applied from the toes to the trunk. Under certain conditions the bandage can be only partially or may be not at all applied. When a tumor exists, or when septic infiltration is present, pressure should only be exercised not quite to the diseased portion for fear of driving septic matter into the vessels. After injuries attended with great destruction, crushing, or pulpification, of course the Esmarch bandage is not applicable, and one must trust to elevation to save as much blood as possible.

While the member is elevated, or before the Esmarch bandage is removed, the rubber-tubing constriction is applied.

The object of this constriction—and this is the chief point in the method—is the absolute occlusion of every vessel at the level of the hip-joint safely above the field of operation.

To prevent any possibility of the tourniquet slipping, Wyeth employs two large mattress-needles or skewers, about three-sixteenths of an inch in diameter and ten inches long, one of which is introduced one inch below the anterior superior spine of the ilium and slightly to the inner side of this prominence, and is made to traverse superficially the muscles and fascia on the outer side of the hip, emerging on a level with and about three inches from the point of entrance.

The point of the second needle is made to enter one inch below the level of the crotch, internal to the saphenous opening, and, passing squarely through the adductors, comes out an inch below the tuber ischii. The points are at once shielded by bits of cork to prevent injury to the hands of the operator. No vessels are endangered by these skewers. A piece of strong white-rubber tube, half an inch in diameter and long enough when tightened in position to go five or six times around the thigh, is now wound very tightly around and above the fixation-needles and tied. If the Esmarch bandage has been employed, it is now removed.

In the formation of flaps the surgeon must be guided by the condition of the parts within the field of operation. When permissible, the following method seems ideal: About six inches below the tourniquet a circular incision is made, and this is joined by a longitudinal incision, commencing at the tourniquet and passing over the trochanter major. A cuff that includes the subcutaneous tissues down to the deep fascia is dissected off to near the level of the trochanter minor. At about the level of the trochanter minor the remaining soft parts,

together with the vessels, are divided down to the bone by a circular cut, and, in order to facilitate the search for the vessels, the soft parts are rapidly removed from the femur for several inches below the line of the divided muscles. At this stage of the operation the larger vessels, veins as well as arteries, should be tied with good-sized catgut. As suggested by Professor Murdoch, of Pittsburg, Wyeth leaves the entire extremity intact and uses the full length of the limb as a lever in dislodging the head of the bone.

When the larger and easily-recognized vessels have been secured, the muscular attachments to the upper extremity of the bone are lifted off with scissors or knife, keeping along very close to the bone. Holding the soft parts away with retractors, the capsular ligament is exposed and divided in its circumference. Forcible elevation, abduction, and adduction of the thigh permit the entrance of air into the socket and at the same time rupture the ligamentum teres, and the disarticulation is thus easily and rapidly effected.

Properly conducted up to this point, not a drop of blood has escaped, except that which was in the limb below the constrictor when this was applied. If now the tourniquet be carefully and gradually loosened, each bleeding-point may be determined and the forceps applied as required until the tube is entirely removed.

Should any difficulty be encountered in the effort at enucleation (which is scarcely possible), the same precaution in securing all bleeding-points should be exercised in removing the tourniquet, and enucleation completed with the tourniquet out of the way.

There remains the closure of the wound, with the usual precaution of drainage. Wyeth prefers silk-worm-gut for suture material, and one good-sized rubber drain from the acetabulum out through the most dependent part of the wound.

#### TREATMENT OF ALOPECIA.

FERRAS (*Annales de Dermatologie et de Syphiligraphie*, tome iv., No. 10) holds that alopecia should be treated not only by local applications, but by remedies which influence the entire system. He commends baths, thirty to forty minutes' duration, of strong sulphur-water. These are followed by massage for ten or twenty minutes and hot spray lasting for from three to five minutes. A half-pint of sulphur-water is taken morning and evening. Locally, he commends the use of tincture of iodine and hot sulphur-water sprays.

#### SUCCESSFUL TREATMENT OF SEPTIC THROMBOSIS OF THE LATERAL SINUS.

VICKERY (*British Medical Journal*, No. 1717, 1893) reports a successful operation for the relief of septic thrombosis of the lateral sinus, calling attention to Lane's seven successes out of eight operations.

The patient was a boy of eight years, who had always been healthy, with the exception of slight bilious attacks. About two years ago he had an attack of measles. He had suffered from intermittent purulent discharges from the right ear. In June, 1893, the discharge stopped, and was followed by severe earache, slight rise of temperature, puffiness over the parotid region in front of the tragus and behind the angle of the jaw, and tenderness on palpation in the same region. This was not noted over the mastoid. In a few days there was some subsidence of local symptoms, but this was shortly followed by distinct rigor, pain in the neck, and stiffness. The rigor was repeated; the temperature ran up to 104.6° F., pulse to 120. The neck was rigid, distinctly swollen, and on palpation tender; enlarged glands were felt, extending from below the pinna down to the middle of the neck, along the carotid sheath. Vomiting, rigors, fever, and the other symptoms continued for several days. Operation was performed June 19. A three-inch incision was carried along the anterior border of the sternomastoid, the centre of the incision being at the level of the cricoid and exposing the internal jugular vein, shelling out some inflamed glands on the way. No thrombosis was found, but the blood-stream was apparently very sluggish. A ligature was placed round the vessel at the lower end of the wound, when the vein immediately collapsed. This clearly pointed to blocking of the circulation on the cerebral side. A semicircular flap was dissected down and a trephine applied, the centre of the instrument being over the posterior inferior angle of the parietal bone. The sinus was seen to contain fluid, but as it had a yellowish appearance, as if it might contain pus, a free incision was made into it. If there was any pus, it came with the first rush of blood. The free hemorrhage was immediately stopped by a pad of iodoform gauze, and then uniting the flap over the pad, tying the first half of the ordinary surgeon's knot and leaving the end long. The neck wound was sutured and dressed. Pulse and temperature dropped promptly. His pain was relieved, but on the following evening there was a rigor, accompanied by vomiting,

purging, a rise in temperature and pulse-rate. Temperature dropped during the night, pulse keeping rapid. The following day there was noted a tender swelling on the palmar surface of the first phalanx of the middle finger, extending on to the palm. No fluctuation was then apparent. On the afternoon of that day there was another severe rigor, accompanied by purging and vomiting. On the evening of the same day his temperature was normal, his pulse stronger. Ultimately the palmar abscess was incised. This was followed by one or two rigors. The patient finally made a good recovery.

Vickery states that the explanation of the case seems to be that there was a septic thrombosis of the lateral sinus sufficiently advanced to have reached the general circulation before operation, and to have occasioned the palmar abscess and the rigor subsequent to the first operation.

In relation to this case, Marsh reported a similar one in which opening of the mastoid antrum and evacuation of fetid pus had not been followed by improvement. To prevent further purulent absorption the internal jugular was exposed and ligated. The operation was not followed by bleeding, showing that the lateral sinus was blocked. This vessel was cleared out as far as possible; but at the time of the report the child's condition was not materially improved.

#### TREATMENT OF PRURITUS.

In the discussion of a paper on this subject by BRONSON a number of interesting points are brought out. Bronson held (*Journal of Cutaneous and Genito-Urinary Diseases*, vol. xi., No. 135) that the underlying condition of pruritus is hyperæsthesia, hence the prime indications in the treatment are to allay or annul excess of nervous excitement. Measures to remove local excitants include such as directly tend to prevent scratching. To admonish the patient to restrain from this is usually of little avail. Restraint may be possible during waking hours, but at night, when the trouble is always at its worst, and especially during the state of somnolence midway between sleeping and waking, no power can prevent it. It can only be avoided by first mitigating the lesion through the aid of antipruritics. Sedatives, when used internally, are apt to be disappointing, and indeed after their use general hyperæsthesia is usually exaggerated. Narcotics are especially objectionable. Bromides are often

indispensable and may be required in full doses. To avoid the weakening effects of insomnia, sulphonal or some other hypnotic is occasionally needed. In addition, two internal remedies are worthy of mention; these are cannabis indica and gelsemium. Carbolic acid, characterized by Unna as the opium of the skin, is the most useful antipruritic agent possessed by the dermatologist. The following antipruritic oil is warmly commended, and it is stated that it never causes any results more serious than a trifling dermatitis:

R Carbolic acid, ʒi;  
Liquor potass., ʒi;  
Ol. lini., ʒi.  
Sig.—Shake before using.

A drop or two of the oil of bergamot will cover the linseed oil. Salicylic acid and salol act much as does carbolic acid. Thymol is often valuable, but also is irritating to sensitive skins.

Pruritus hyemalis is prevented by guarding against cold, since the sole cause of this distressing affection is lowered temperature.

Hyde, in commenting upon these conclusions of Bronson, stated that he has long since dropped cocaine, since it is extremely liable to develop the habit. He alluded to two methods of treatment, both of value. The first consists in exclusion of air. Thus some of the successful pastes depend for their beneficial effect upon this action. Another method of relieving pruritus, when it is circumscribed and strictly limited to one side of the body, is in treating the other and corresponding side with substitutive stimulants. A case is narrated in which a patient had long suffered from an almost intolerable pruritus of one leg. Relief was obtained only after stimulating the other corresponding side of the body. Hyde called attention to gout as a frequent cause of pruritus. Next in importance he names diabetes.

Corlett states that in prurigo hyemalis the internal administration of ichthyol has apparently given him excellent results. He applies lanolin to the skin locally after the surfaces have been bathed. Resorcin has given better results than any other drug. This is used in the strength of three to five per cent., and is applied in aqueous solution.

Morrow condemns the use of gelsemium, and states that he has had excellent results from the employment of the hot-water bag applied to the spine. Indeed, he lauds this treatment above all others in certain obstinate cases occurring in people. Among the local remedies he has had the best results from a combination of car-

bolic acid and camphor. He uses this in the strength of one and two drachms of each drug to the ounce of zinc ointment. Another excellent remedy is salicylic acid made up in the form of wax and spermaceti, in the form of an ice, or in rose-water in the form of a solution.

Hardaway states that, in addition to the remedies already mentioned, there are three drugs which he gives with sometimes successful results. These are quinine in 10- or 15-grain doses at night, wine of antimony given in divided doses during the day, and pilocarpine by the mouth or hypodermically, especially where the skin is harsh and dry. He holds that carbolic acid as a local application stands at the head of the antipruritics, but prefers to have it sprayed on by means of an atomizer.

Denslow calls attention to the value of ergot.

## Reviews.

---

A MANUAL OF PRACTICAL HYGIENE DESIGNED FOR SANITARY AND HEALTH OFFICERS, PRACTITIONERS, AND STUDENTS OF MEDICINE. By W. M. L. Coplin, M.D., and D. Bevan, M.D. Illustrated. Philadelphia: P. Blakiston, Son & Co., 1893.

The average book upon hygiene is either devoted to trivialities and designed for common-school purposes, or, like Parke's celebrated manual, is so thorough and exhaustive as to be exhausting as well to any one who desires to obtain scientific information without reading a large amount of statistics and studying many pages of text. The authors of this book of four hundred and fifty pages have endeavored to fill the space lying between these two forms of hygienic literature, so to speak, and we think they have succeeded. Many of the illustrations are original, being drawn by Dr. Bevan, and the authors have taken much pains to include in the work new facts concerning climate and cognate subjects. Their positions at present and in the past, in connection with the government service and as pathologists or bacteriologists to large hospitals, have given them ample opportunities to study the needs of the class of persons for whom the book is destined, and the large experience they have had in teaching institutions has taught them in turn how to state facts in such a way that the scholar may readily grasp them. We feel confident that this book will be appreciated by those for whom it is written, and that it will be a constant source of credit to its indefatigable and careful authors.

MANUAL OF PHYSICAL DIAGNOSIS FOR THE USE OF STUDENTS AND PHYSICIANS. By James Tyson, M.D. Second edition, revised and enlarged.

Philadelphia: P. Blakiston, Son & Co., 1893.

If Dr. Tyson has one *forte* above another it is his ability to use his pen in such a way as to make descriptions of medical facts clear and interesting to the student or physician. His articles are perhaps more widely quoted than those of almost any other writer in the medical journals of the day, and the various brochures which he has published from time to time have been read by the profession with avidity. The second edition of his little work on "Physical Diagnosis" bids fair to be even more successful than his other contributions to medical literature. The ideas are clearly expressed, and a certain number of clear diagrams accompany the text to make the descriptions readily understood. The smallness of the work, its completeness, and its comparatively low cost, added to the advantages which we have already named, will be strong aids in causing its still further employment during student days.

BURDETT'S HOSPITAL ANNUAL AND YEAR-BOOK OF PHILANTHROPY. 1893.

London: The Scientific Press, Limited.

To those who are interested in the subject of hospital management this book will bring a large amount of exceedingly valuable information. In addition to its text, which is very carefully prepared, a number of tables are given, showing the cost of maintaining various kinds of hospitals all over the world and the names of nearly all the prominent hospitals in the world, especially in the English provinces and in America, with information concerning their staffs, income, cost of maintenance, and methods of nursing. While it deals naturally to a great extent with English institutions, far more credit has been given to and pains taken in regard to American hospitals than is ordinary in such international publications.

THE PHYSICIAN'S VISITING-LIST FOR 1894.

Philadelphia: P. Blakiston, Son & Co., 1893.

Forty-three years of experience in preparing a list for the physician has enabled the publishers of this well-known pocket-book to arrange a large amount of condensed information without making their book difficult of being carried in the pocket. It is especially to be commended for the pliability of its cover, the lightness of the paper which it contains, and the conveniences offered for entering a record of patients.

THE MEDICAL NEWS VISITING LIST, 1894. THIRTY PATIENTS PER WEEK.

Philadelphia: Lea Brothers & Co., 1893.

This "Visiting-List," which we have found to be very useful, contains, in addition to its well-arranged blank pages, information, in a brief form, in regard to the period of dentition, estimating the day of confinement, the thermometric scales, weights, and measures, including the metric system, two or three pages upon the examination of the urine, a page on artificial respiration, a table of the eruptive fevers, a list of poisons and their antidotes, and, finally, a table of doses arranged in two columns, which give the amounts in Troy weight and the metric system. One of the most useful parts of the List to the physician who is called to an emergency is the brief space given to the ligation of arteries, accompanied by a diagram showing where the incision should be made for the ligation of blood-vessels. Notwithstanding the large amount of material contained between the covers of this book, it is much less bulky than would be supposed and can be readily carried in the pocket.

A MANUAL OF DISEASES OF THE EAR. By G. P. Field, M.R.C.S., Aural Surgeon to St. Mary's Hospital, London. Fourth edition. Three hundred and seventy-one pages. Illustrated with colored plates and woodcuts.

Philadelphia: Lea Brothers & Co., 1893.

The new edition of this excellent manual of the ear and its diseases covers the field of otology in nineteen concise and practical chapters. We desire to call attention to the enormous amount of excellent material that this little volume contains and the instructive and comprehensive manner in which the subject is handled. The author's views are so plainly and forcibly expressed that the student and general practitioner of medicine cannot afford to be without their teaching and careful guidance if he would do the justice to his patient that the present advanced state of otology legally demands.

Some forty pages are devoted to a careful review of the minute anatomy and physiology of the ear. The subject of chronic suppurative inflammation and its results is ably discussed in four chapters, which comprise the most important part of the work. In these chapters will be found sound and trustworthy advice on aural polypi, facial paralysis, caries and necrosis, mastoid and brain abscess, phlebitis and pyæmic thrombosis of the lateral sinus, as well as visceral sequelæ, the result of chronic aural discharge. We are pleased to find the author

so strong an advocate of properly-conducted irrigation in suppurative diseases of the ear, as this is undoubtedly the only means by which we can obtain thorough asepsis in a large proportion of our cases.

A wholesome conservatism is a marked feature throughout the book, and yet it is gratifying to find that in selected cases the author strongly advocates the intratympanic surgical methods that have met with such marked success in the hands of many aurists in this country. This observation applies particularly to the treatment of that large class of otherwise incurable cases which are discussed under the head of "Chronic Suppurative Inflammation with Caries and Necrosis." To quote the exact views of the author, "After sequestra, granulomata, and cholesteatomatous masses have been removed, all carious areas must be cautiously but thoroughly *curetted*."

The brief space allotted for this review will not permit of extended comment; suffice it to say, however, that within the covers of this book will be found information sufficient to supply the needs of the student and practitioner of general medicine in all practical matters pertaining to diseases of the ear.

S. MACC. S.

MENTAL NURSING: A TEXT-BOOK FOR ASYLUM ATTENDANTS AND NURSES. By William Harding, M.D. London: The Scientific Press, Limited, 1893.

This small volume consists of a number of exceedingly practical chapters upon the character and the management of the insane from the stand-point of the nurse. The first three chapters consist of the discussion of some important elements of anatomy and physiology, and also deal with the nature of fractures, wounds, hemorrhage, heart-disease, food, strangulation, poisoning, burns, etc. Following this the nurse receives some very practical hints regarding the nature of insanity, special stress being laid upon the fact that insanity is a bodily disease. Next comes some very practical advice on ventilation, warmth, cleanliness, the manner of feeding the insane and their general management. Very practical advice is given regarding the tact to be observed in dealing with delusional and with dangerous lunatics. The matter of social entertainment for the insane, night nursing, and the management of the bedridden insane completes these very valuable lectures.

The book is one which not only commends itself to asylum nurses, but to general nurses as well.

F. X. D.

OUTLINES OF INSANITY. DESIGNED FOR THE USE OF MEDICAL PRACTITIONERS, JUSTICES OF THE PEACE, AND ASYLUM MANAGERS. By Francis H. Walmsley, M.D.

London: The Scientific Press, Limited, 1893.

These outlines, being intended for lay as well as medical readers, are as much as possible divested of technicalities. The subject is presented in a concise, clear, and somewhat popular manner. The classification of insanity adopted is, of course, purely clinical, types only being considered.

The first and second chapters deal with normal and abnormal mental action, while the insanities themselves are considered in the following order: Melancholia, mental stupor, mania, puerperal insanity, dementia, weak mind, alcoholic insanity, epileptic insanity, general paralysis of the insane. The final chapter is devoted to the causes of insanity. An appendix then follows upon the care and treatment of the insane, lunatic hospitals, and upon actions in lunacy against medical men.

The book is exceedingly practical, and not only of value to the lay reader, but also to students and men in general practice whose time is limited, or to whom larger works upon insanity are inaccessible. F. X. D.

ANNUAL OF THE UNIVERSAL MEDICAL SCIENCES. Edited by Charles E. Sajous, M.D., and seventy associate editors, assisted by over two hundred corresponding editors, collaborators, and correspondents. Illustrated. Five volumes.

Philadelphia, New York, Chicago, and London: The F. A. Davis Company, 1893.

The appearance of the "Annual of the Universal Medical Sciences" is an event looked forward to with eagerness by practically every writer and advanced thinker in the country, and no doubt each of these, on the receipt of his volumes, turns to see if his most cherished contributions to medical literature have received due credit. In the great majority of cases he will not be disappointed, though even five volumes, each numbering about five hundred pages, do not give enough space to include all that has been contributed to medical science during the year. The omissions are, for the most part, unimportant.

To the active editorial staff have been added Dujardin-Beaumetz, Richardson, Lépine, Buxton, Apostoli, Obersteiner, and others of equal note, thus giving the production an international character.

In the preface the editor pays a well-deserved tribute to the value of the scientific work contributed by American authors, and calls attention to the fact that these works, for the most

part, remain unseen on the continent of Europe.

In the first volume are taken up Diseases of the Lungs and Pleura, the Heart and Blood-Vessels, the Alimentary Tract and its Associated Glands, the Urinary Apparatus, Diabetes, Fevers, Rheumatism and Gout, Diseases of the Blood, and certain of the contagious diseases. Among the list of editors the names of Dolley, Benjamin Ward Richardson, Dujardin-Beaumetz, James Wilson, and F. P. Henry are notable, and assure the thoroughness and accuracy with which their several subjects are summarized.

The second volume is taken up with Diseases of the Nervous System, of the Genital Tract of Women, Obstetrics, Diseases of the New-Born, and of Infancy and Childhood. In this volume the work of Landon Carter Gray, writing of Diseases of the Brain; of Montgomery, upon Diseases of the Ovaries and Tubes; of Baldy; and of Starr and Powell, upon Dietetics and Gastric Disorders of Infancy, is particularly to be commended.

Volume III. is devoted to Surgery. Pilcher and Lloyd have summarized all that has been contributed to the Surgery of the Brain, the Spinal Cord, and the Peripheral Nerves. Gaston has collected the contributions of the year on Thoracic Surgery. John Packard has given an admirable *résumé* of Surgery of the Abdomen. Kelsey contributes a very brief and most excellent section upon Diseases of the Rectum and Anus. Keyes and Fuller have admirably summarized Genito-Urinary Surgical Diseases. The subjects of Syphilis and Chancroid are completely covered by J. William White, assisted by Furness: White's name is a sufficient guarantee of the value of this article. Lewis and Reginald Sayre have summarized the advances in Orthopædic Surgery. Stimson, on Fractures; Matas, on Aural and Facial Surgery, this article being especially full; Laplace, on Surgical Mycoses; Tiffany and Warfield, on Surgical Diseases; Booth, on Traumatic Neuroses; Packard, on Antiseptics and Surgical Dressings; and Buxton, on Anæsthetics, complete this volume. Laplace's article on Mycoses is particularly noteworthy.

The fourth volume is taken up with Diseases of the Skin, Eye, Ear, Nose and Throat, Larynx and Oesophagus, Thyroid Gland, Local Medicine, Demography, Microscopy, Histology, and Bacteriology. Van Harlingen and Oliver, as usual, have contributed, each in his own department, articles which for thoroughness and discrimination are surpassed by none in the entire selection. The section on Intubation

ing the packing is dispensed with and the wound dressed antiseptically.

In following out this radical method of treating mammary abscess a large amount of healthy gland tissue must necessarily be destroyed; and the removal, as well as repacking, of any large quantity of gauze is a painful operation, especially so to women during the puerperium. We know from practical experience how trivial are the causes which elevate a patient's temperature after confinement, and dressings which are painful and frequently repeated must necessarily have a depressing effect during this period.

In private practice, unless it be a matter of life and death, the question of how much pain and discomfort we can avoid for our patients is one always to be carefully considered and an important factor in our success, and one frequently overlooked by men of large hospital experience.

On the other hand, I must confess that the simple opening of a mammary abscess, under all antiseptic precautions, and the thorough drainage with gauze or tube, is not as satisfactory an operation in this region as in other parts of the body. Owing to the large amount of areolar tissue, the induration around the abscess is apt to be considerable, and frequently becomes the source of other foci of pus, which, in turn, we are obliged to evacuate. If the patient be of a strumous constitution, or weak and debilitated, this condition of suppuration may last for days and the breast become riddled with sinuses.

Now, the treatment which I have adopted during the last few years is less painful, more simple, and has given in my hands most satisfactory results. Mammary abscesses will take place in the hands of the most skilful obstetricians and notwithstanding the most scrupulous care and attention to the nipples. The trouble, I believe, is not so much due to the entrance of pyogenic bacteria into the ducts, since these have been conclusively shown to be present normally in the milk before its exit from the gland, as it is due to local obstruction in the ducts or a stasis in the circulation of the capillaries and lymphatics.

During the state of congestion the liberal use of acetate of potassium and the local application of hot flaxseed poultices will frequently relieve vascular engorgement and prevent suppuration; but as soon as the temperature fluctuation or local oedema points conclusively to the presence of pus, a few simple incisions under all antiseptic precautions must be practised and a moist antiseptic dressing applied. But at the end

of twenty-four or thirty-six hours it is my custom to discard all antiseptic dressings and apply every three or four hours strips of flannel or lint soaked in hot sterilized spermaceti oil. The discharge of pus will cease within a day or two and the temperature drop to normal, even if the induration does not at once disappear. The strips of lint or flannel are covered with oil silk and firm pressure is applied with a bandage. The objectionable odor of the oil can be disguised with a few drops of bergamot or gaultheria. It is a dressing much more comfortable and grateful to patients than the moist bichloride or iodoform gauze.

In treating the simple acute adenitis so frequently met with in strumous children, this oil thickly spread over a flaxseed poultice has given most excellent results.

I do not pretend to explain how or in what manner the oil acts, but the fact remains that in my hands it has been so far the most satisfactory method of treating mammary abscess.

D. T. LAINÉ.

MEDIA, PA., December, 1893.

#### NATURE AND TREATMENT OF ULCERS OF THE CORNEA COMPLICATED WITH HYPOPYON.

VALUDE makes the following abstract of a Paris thesis, by Belohous (*Annales d'Oculistique*, October, 1895). The author, after showing the different known methods of treatment of this affection, lays down the following general principles: In children, ulcers of the cornea without hypopyon, being closely connected with scrofula, ought to be treated with a tonic medication and with suitable topical applications. Ulcers with hypopyon in adults are of an infectious nature, and demand, above all, antiseptic treatment. In adults, the dry occlusive dressing with iodoform used by Valude succeeds very well in all ulcers with hypopyon uncomplicated with blennorrhoea of the lachrymal sac, with conjunctivitis, or with chronic rhinitis and ozaena. In these cases the prognosis with this method of treatment is favorable. Complicated hypopyon ulcers resist every antiseptic treatment so long as the infectious conditions which are the cause are not cured. Paracentesis of the cornea and actual cauterization are indicated only for complicated hypopyon ulcers which resist ordinary treatment, and under these circumstances the prognosis is gloomy.

### THE TREATMENT OF GLEET, DUE TO PRESENCE OF STRICTURES OF LARGE CALIBRE.

BY H. M. CHRISTIAN, M.D.,  
Chief of Genito-Urinary Clinic, University of Pennsylvania,  
service of Dr. Edward Martin.

**S**TRICTURE of the urethra is considered at the present day by all authorities in genito-urinary surgery to be one of the most frequent causes in the production of gleet. When the

stricture is located in the penile urethra, posterior to the corona glandis, gradual dilatation, by the frequent passage of sounds, will, in the vast majority of cases, cure the gleet. In those cases, however, of gleet depending upon the presence of strictures of large calibre at or near the meatus, simple dilatation by sounds is not apt to prove very successful in stopping the discharge.

The unsatisfactory results obtained from dilatation of strictures in this locality depends, in the first place, upon the fact that they belong, for the most part, to that class of stricture known as resilient, or elastic,—a form of stricture which is, as is well known, not amenable to simple dilatation. A second cause for the fail-

ure of dilatation to cure these strictures is to be found in the fact to which Dr. J. W. White has called attention, that, owing to the very abundant nerve-supply of the glans penis, dilatation to anything like the proper calibre gives rise to considerable pain and irritation, sufficient at times to produce a simple urethritis, or marked reflex irritation in the deep urethra.

Another form of stricture in this locality, which often acts as a powerful factor in the production of gleet, is the congenital stricture of the meatus. About twenty per cent. of the cases of gleet treated at the Genito-Urinary Dispensary of the University were found to present a condition of abnormal narrowing of the meatus. Division of the meatus to the proper calibre was invariably followed in a short time by a cessation of the gleet discharge.

In all cases of chronic urethral discharge presenting themselves for treatment at the Dispensary, where the bulbous explorer demonstrates the presence of either of the above-mentioned forms of stricture, the practice is to immediately divide the stricture to what is considered the normal calibre. This plan of treatment has almost invariably been followed by a very rapid cure of the gleet.

The books of the Dispensary contain the histories of forty cases of chronic urethritis treated in this manner during the past year and a half, all of which recovered entirely in from two to four weeks after the strictures were divided.

The following is the history of a few of the cases treated, and may be taken as a fair sample of the other cases.

It will be noted that the scale adopted to measure the normal dilatability of the urethra is that proposed by Dr. White, and differs from that employed by Dr. Otis in the fact that it is graded lower, as follows:

A penis, the circumference of which one inch posterior to the corona is three inches, should take normally a twenty-six to a twenty-eight sound (French scale). When it is three and-a quarter inches, a twenty-eight to a thirty sound; three and a half inches, thirty-two to thirty-four sound.

CASE I.—R. E., aged nineteen; has had gonorrhoea twice; last attack followed by gleet.

*Present Condition.*—Meatus glued in morning for past nine months; no history of frequent or imperative urination; clap shreds in first portion of urine passed.

*Examination.*—C. P. (circumference of penis),  $3\frac{1}{2}$  inches; meatus, 18 (F.) calibre.

*Treatment.*—Meatus divided to 30, followed by daily passage of 30 sound through meatus for four days, then at intervals of three days.

Gleet cured in two weeks.

CASE II.—P. H., aged thirty; two attacks of gonorrhoea; has had gleet discharge in morning for past seven months; clap shreds in urine; no frequent or imperative urination.

*Examination.*—C. P.,  $3\frac{1}{4}$ ; meatus, 14 calibre.

*Treatment.*—Meatus cut to 28, followed by passage of 28 sound in the usual method.

Discharged cured in ten days.

CASE III.—H. B., aged twenty-three; gonorrhoea three times; has had gleet for two months; been using injections; complains of morning drop; no discharge through the day.

*Examination.*—C. P.,  $3\frac{1}{4}$ ; stricture, 22 calibre, one-half inch from meatus.

*Treatment.*—Stricture divided to 28, followed by passage every four days of 28 and 30 sound.

Discharged cured in two weeks.

CASE IV.—S. G., aged twenty-two; gonorrhoea four times; last attack complicated with epididymitis and posterior urethritis; has had gleet for past four months.

*Examination.*—C. P.,  $3\frac{3}{4}$ ; stricture, 24 calibre at one-quarter of an inch.

*Treatment.*—Stricture cut to 32, followed by passage of 32 and 34 sound at regular intervals.

Cured in five weeks.

CASE V.—P. G., aged thirty; has had gonorrhoea three times; contracted last attack one year ago; discharge profuse for one month; had posterior urethritis; has had gleet discharge in morning for past ten months.

*Examination.*—C. P.,  $3\frac{3}{4}$ ; stricture, 26 calibre at one-half inch; no deep stricture.

*Treatment.*—Stricture divided to 32, followed by passage of 32 and 34 sound at regular intervals.

Discharge ceased at end of three weeks.

These few cases, taken at random from the records of the Dispensary, may be considered fairly typical, an almost equal amount of success following in all cases in which this line of treatment was pursued. It should be noted that in the examination of all of these cases great care was taken not to consider as strictures either points of physiological narrowing of the urethra or localized patches of granular urethritis.

The mode of procedure is the same in the treatment of all of these named cases of narrowing at or near the meatus. Having ascertained

by means of bulbous bougies the presence of a stricture at or near the meatus,—i.e., within one-half inch of the meatus,—the anterior urethra is irrigated by a warm bichloride of mercury solution (1 to 20,000). The glans penis is next washed with alcohol. A pledget of cotton tightly wrapped on a match-stick and dipped in a ten-per-cent. solution of cocaine is introduced one-half inch within the meatus and allowed to remain for about fifteen minutes. The stricture is then divided on the floor of the urethra to the proper calibre. The instrument used for this purpose is an ordinary blunt-pointed tenotome with convex cutting-edge.

In dividing these strictures the normal calibre of the urethra should be considered as obtained whenever the bulbous explorer, representing in size such calibre, passes the site of the stricture without catching.

The subsequent treatment consists in the passage of proper sounds daily for three days, afterwards at intervals of four to five days.

#### NOTE ON STRYCHNINE AS A CARDIAC AND RESPIRATORY STIMULANT.

BY W. H. WASHBURN, M.D., MILWAUKEE, WIS.,  
Professor of the Principles and Practice of Medicine, Wisconsin  
College of Physicians and Surgeons.

**D**URING my term of service at the Emergency Hospital this winter a case was brought in which illustrates so well the physiologic effects of strychnine that I deem it of sufficient interest to place the facts on record. At eight o'clock on the evening of December 1 I was hurriedly called to the hospital. On my arrival, a few minutes later, I found the patient, a rather large, robust-appearing man, upon the table in the operating-room, and to all appearances about to breathe his last. His eyes were upturned and the dilated pupils did not react to light; his respirations were exceedingly shallow, irregular, and scarcely perceptible; and he had the weak, uncertain, irregular pulse of a dying man. There was no history at all with the case, the patient having been brought in by the police in this condition. There appeared to me to be but one thing indicated, and that was a powerful cardiac and respiratory stimulant, though there appeared to be not the remotest probability that any good purpose would be thereby accomplished. I accordingly injected subcutaneously  $\frac{1}{10}$  grain of strychnine, and then for a few minutes practised artificial respiration. Within a very few

minutes there was a most remarkable change in the whole aspect of the case, not only in the appearance of his countenance, but in the character of his pulse and respiration. The respirations soon became so deep, regular, and vigorous that I was enabled to reach the conclusion that the man was suffering from chloroform narcosis, the odor of his breath indicating what he had swallowed. One subsequent injection of  $\frac{1}{10}$  grain of strychnine was given about an hour after the first, and at ten o'clock I had the satisfaction of being able to communicate with the patient, who, after a great deal of coaxing and threatening, was induced to confess that he had swallowed two ounces of Squibb's chloroform with suicidal intent. The bottle was afterwards picked up near the place where the patient was found by the police.

The patient was removed to the County Hospital the following day with an acute gastritis. He began vomiting about one hour after the administration of the first hypodermic injection. I believe this case is remarkable for the large amount of the drug swallowed without being followed by a fatal result, this favorable outcome of the case, however, being, as I believe, attributable solely to the antidotal effect of the strychnine.

H. C. Wood, in the eighth edition of his "Therapeutics," speaks of three cases of recovery after the ingestion of large doses of chloroform,—in one case one ounce, in the second case two ounces, and in the third case three ounces. In discussing the treatment of such cases as the above he makes no mention of strychnine, a drug whose physiologic action is such as to render it, as it appears to me, the remedy *par excellence* in this emergency. And if strychnine is thus indicated, and is as efficacious as it appears to have been in this case, where the chloroform has been taken into the body by way of the stomach, why is it not the proper remedy to use when alarming symptoms occur during surgical anæsthesia? I am able to add that in one such case, where the patient did not recover well from the chloroform anæsthesia, but appeared blanched and with an almost imperceptible pulse, rapid improvement followed upon the hypodermic injection of  $\frac{1}{10}$  grain of strychnine. Too much importance cannot, in my opinion, be attached to the administration of this drug under these circumstances, and I feel satisfied that when this is more fully realized by the profession in general, some cases, at least, of death on the operating-table from chloroform narcosis may be averted.

*CHOLECYSTENTEROSTOMY, WITH REMARKS ON INTESTINAL ANASTOMOSIS AND EXHIBITION OF A NEW APPROXIMATION BUTTON.*

READ BEFORE THE PHILADELPHIA COUNTY MEDICAL SOCIETY,  
JANUARY 24, 1894.

BY DAMASO LAINÉ, M.D.

I SHALL first briefly read the report of the following case, and then make a few remarks on intestinal anastomosis:

Mrs. L., aged forty-five, married; one child eleven years of age. In the month of October, 1892, she became suddenly ill with the following symptoms: Intense abdominal pain, paroxysmal in character, vomiting, and constipation. Jaundice appeared on the second day, as well as marked discoloration of the urine and clay-colored stools. This was followed by a severe chill on the sixth day, with a temperature ranging between  $104^{\circ}$  and  $105^{\circ}$  F. As the jaundice in this case was of the most marked type, coming on suddenly, with no previous history of emaciation, vomiting, or pain, and as the temperature and chills persisted for several days, I decided to send the woman to the Jefferson Hospital, under the care of Professor Wilson, venturing on the diagnosis of acute obstructive jaundice with Charot's hepatic fever, and in the hope that an early operation, at least of an explorative character, would be performed. She remained in the hospital about nineteen weeks, the chills and jaundice persisting, with progressive emaciation. On consultation with Drs. Keen and Brinton, as I have since learned from Professor Wilson, the question of operation came up on several occasions, but the possibility of malignancy and the woman's weak condition precluded for the time being all operative interference. Eventually her jaundice disappeared. She became apyretic and made a good recovery. She was dismissed from the hospital about the 1st of February, 1893.

Up to the time I saw her again, which was July of last year, she had remained in good health and gained several pounds in weight, but on the vomiting, jaundice, chills, and fever suddenly returning, I decided to perform cholecystostomy at once. This I was able to do, with the assistance of Drs. Stoeber and Jefferis, of Chester, and removed a large gall-stone from the distended bladder. The concretion was of unusual size and marked by large facets, indicating at least the possibility of the previous existence of other stones in the bladder or present now in the gall-ducts; but as I could detect no others with my finger through the

foramen of Winslow, I came to the conclusion that the obstruction must be due to cicatricial contraction.

We frequently read of the possibility of such an occurrence, but whether this has been clearly demonstrated to have occurred or not I am not at all certain. (Since writing the above I find that Osler mentions that this condition is extremely rare.)

The liver in this case was enlarged and the bladder enormously distended, holding, as well as I could judge, about a pint of clear, thin bile.

The fundus of the bladder was stitched to the abdominal walls by a double row of sutures previous to making the incision into its walls. A long drainage-tube was inserted and the wound closed with silk-worm gut. Whether the fever which accompanies these cases is due to a ferment (Charot's theory) or to the effects of the bacterium coli commune, or is of nervous origin due to local irritation, it certainly disappeared within a few hours after the operation. Large quantities of bile continued to be discharged through the drainage-tube, soaking the bedclothes and necessitating frequent changes in the dressings. The patient was up and out of bed on the twentieth day, and had returned to her usual occupation at the end of the month.

As the stools remained clay-colored and she suffered very much from gaseous distention of the bowels, and the daily discharge of such large quantities of bile became extremely annoying to her, I decided to close the fistulous opening. On the 15th of September I put her under ether again and made a Y-shaped incision over the region of the gall-bladder, across the old cicatrix. On entering the abdominal cavity I pushed upward the greater omentum and drew out a small knuckle of intestine, as close to the duodenum as I could judge, and performed cholecystenterostomy, using the smaller size Murphy button. The fistulous tract running through the abdominal walls I curetted and closed at once with a circular purse-string stitch. The abdominal wound was closed without drainage. The temperature remained about  $99\frac{1}{2}^{\circ}$  and  $100\frac{1}{2}^{\circ}$  F. for several days, but otherwise she made an uninterrupted recovery. On the twelfth day, after receiving an enema, the button was passed. Since that time she has been in very good health, able to attend to all her duties as a housekeeper, and has gained some fifteen pounds in weight.

One of the most noticeable things observed in connection with the gall-bladder at the time of both operations was the fact that every needle

puncture made into its walls remained patulous, the bile oozing out in large drops, showing conclusively that aspiration of this organ cannot be considered as safe an operation as we are led to believe from the advice of recent text-books. Such a procedure, judging from the above facts, should be considered unsurgical and unjustifiable under any circumstances.

It is hardly within the scope of this article to give more than an imperfect *résumé* of the work which has been done in intestinal anastomosis within the last few years. We must date the most important era in this branch of surgery from the introduction of the Lembert suture in 1825. He was the first surgeon to demonstrate conclusively that intestinal wounds unite by adhesion between the serous surfaces. Others have claimed priority, and during the last decade quite a number of sutures and mechanical means have been devised; but they all depend for their success upon the law formulated by this surgeon, that intestinal wounds must unite by primary adhesions between the serous coats.

Next comes the period of Lister, who taught us that living tissues must be kept aseptic if we expected Nature to perform successfully her reparative work.

With these facts before us, we may safely consider certain primary laws which are applicable to all cases of intestinal anastomosis, and upon the strict observance of which will in a great measure depend our success.

1. Absolute cleanliness.
2. Perfect apposition of the serous surfaces which we wish to unite.
3. Rapidity in the execution of our work.

The primary adhesive non-septic peritonitis occurring within a few hours after an operation, and which is so absolutely essential for the perfect union of all intestinal wounds, will not readily take place if infection of the peritoneal cavity occurs; therefore the strict observance of perfect asepsis is of vital importance to the success of any form of intestinal suture or mechanical device. As Nature intended the abdominal cavity to be a closed one and completely lined by a serous membrane, the ideal, in all operations, should be to leave it as far as practicable under the same conditions. As to speed, that, of course, is a matter which will always depend upon individual operators and the degree of proficiency attained by constant practice. The shortening of the time of an operation by any new instrument or suture, all things being equal, should be a strong argument in favor of its introduction. After all, we may safely assert that there is no branch of surgery

which requires such minute attention to details as this one.

It may seem presumptuous on my part to make remarks of this character before such a representative body of surgeons and specialists, but these are the facts which have most forcibly impressed me in my very limited experience in abdominal work. Most cases of post-operative peritonitis do not depend so much on the adversity of fate as on the ignorance or neglect of certain laws. Our failures and not our successes teach the most impressive lessons.

In describing the following sutures I shall freely quote from Senn, who, after all, has done more than any other man in this country towards the advancement of this particular branch of surgery. It will certainly repay the student interested in this line of work to read his article in the *Journal of the American Medical Association*. His remark that the history of intestinal sutures is "replete with stupendous ignorance, clever mechanical ingenuity, and patient experimental research" is but too clearly evident in his exhaustive review of the subject from the time of Celsus to our present day. Therefore I shall only attempt to describe those sutures and mechanical devices conceded by the profession to be of some practical value.

In applying the Lembert suture, one which it is unnecessary for me to explain, it is well to bear in mind the distances at which the stitches should be introduced, not only from each other, but from the margins of the wound. It has been advised by one of our recent text-books that this distance be one-twelfth of an inch, but we should always remember the possibility of cutting off the blood-supply by too close apposition of the stitches, and in this manner retarding the occurrence of that which we wish to take place,—adhesion and vascularization of the parts. Also, the introduction of so many stitches consumes time, without adding materially to the better union of the parts. All needles used in this kind of work should, of course, be round, and the silk of the finest.

Dupuytren's stitch is nothing more than a continuous Lembert suture. Czerny, in 1881, added an extra row to the Lembert suture, which included all the coats except the serous, as the latter includes all except the mucous. By this means he hoped to obtain perfect coaptation of the various layers of the bowel,—a firm union, followed by less cicatricial contraction. The inner suture at the same time would be extraperitoneal, ulcerating in the lumen of the bowel, and not becoming encysted, as does the Lembert. In performing circular enteror-

raphy, the mesenteric side should receive the greatest attention, since here most of the perforations take place.

The right-angle continuous suture of H. W. Cushing is one I have used very successfully in my experimental work upon dogs, when there was a tendency for the muscular and sub-mucous coat to tear. Halstead lays great stress upon the importance of including this last-mentioned layer in all sutures. Mansell's operation is so difficult to understand from a mere description, that I have thought it advisable to demonstrate the three different steps of its application by as many specimens.

Among the numerous mechanical appliances I shall only attempt to describe Murphy's button, Ramage's aluminum rings, the decalcified bone-plates of Senn, with which you are all familiar, and Robson's decalcified bone bobbin.

After a number of experiments made with different substances, Senn found that decalcified bone-plates gave the most satisfactory results. By using these he found that large serous surfaces could be held together, the bones acting as splints, and only a few stitches were required, shortening considerably the time of an operation such as gastroenterostomy, in which so much of it is consumed in suturing.

The openings in the plates are three inches in length, and that in the bowels must be made correspondingly long. This is necessary, in order to overcome as far as possible a certain amount of cicatricial contraction, which takes place, after a time, at the seat of all such operations. The degree of contraction depends upon a variety of causes, the proper correction of which has not thus far been satisfactorily solved. The consequent stenosis at the seat of operation will be in proportion to the amount of the wound left to heal by granulation, and this is a factor which Dr. Murphy claims is greatly minimized by the use of his button, which, by bringing the normal histological elements in close and accurate apposition, allows of the formation of less connective tissue, and consequently less contraction takes place.

To these plates are attached four approximation sutures, two of them armed with needles. When these have been tied, the serous surfaces from the margins of the plates are sewed together with a continued suture. Notwithstanding the large opening obtained by this combination of suture and mechanical support, in a certain number of cases complete closure has taken place. As a substitute for the plates several substances have been introduced,—catgut

rings, segmented rubber, rawhide, cartilage, chromized gelatin, plates made from turnips, potatoes, and horses' hoofs. Some surgeons who had previously advised and used various appliances in performing lateral anastomosis have now entirely discarded them, and depend upon a double row of sutures for the union of such wounds.

Robson's decalcified bone bobbin is but a slight improvement on the ancient methods of end-to-end union, in which a cylinder of cardboard or the dried trachea of a goose was introduced into the lumen of the gut and the wound united by an interrupted or continued suture.

Dr. Ramage's (of Buenos Ayres) aluminum rings operate on the principle of the Murphy button. The ends of the bowel are pressed and held together by the rings, which are operated by a groove and ratchet arrangement. Although they allow of a larger central opening than the button, sloughing must necessarily take place, and it must be slower, from the absence of the elastic pressure between the rings which is present in the Murphy button.

The Murphy button, with which some of you are already familiar, is composed of two hollow, metallic, cup-shaped hemispheres with a stem and central perforation in each one. When clamped together the stems or hollow tubes are telescoped, forming a round, smooth button. In performing an anastomosis the cut ends of the bowel are first stitched with a purse-string suture, which is tied over the stem, the edges of the bowel being tucked in the hollow, cup-shaped depression of the button. When clamped together, which must be done by a certain amount of pressure, the serous coats are brought into perfect apposition. By an extra cup-shaped ring, attached to a spring, a continuous pressure is kept up between the edges of the button. The author claims that by this means a pressure atrophy is produced, and not gangrene of the parts included in the grasp of the instrument. In the course of from eight to fourteen days sloughing takes place and the button passes through the intestinal canal without difficulty. Senn claims that he has known several cases in which the parts approximated by the button were found separated on post-mortem examination. I shall quote *verbatim* what he has to say on this subject:

"Any instrument, suture, or ligature used in effecting the continuity of a wounded or divided bowel that produces gangrene must be looked upon as a source of danger. It is impossible to effect an aseptic necrosis in the interior of the bowel, and dead tissue inhabited by pathogenic microbes always constitutes a source

of danger. It is easy enough to produce gangrene, but we are powerless in limiting its extension in this locality. The limited area of living tissue brought in contact outside of the rings of Denan or the Murphy button will not always prove adequate in the protection of the peritoneal cavity against perforation and its immediate result, septic peritonitis. . . . The size of the button is also a very serious objection. I have operated for intestinal obstruction produced by a gall-stone less than an inch in diameter which had become impacted in the lower end of the ileum, and other surgeons will recall similar instances."

Notwithstanding all the adverse criticism made by Professor Senn and other eminent sur-

to pass, no matter what the degree of cicatricial contraction afterwards, it cannot be so great as to interfere with the ultimate object of the operation. Dr. Murphy has already reported seventeen cases of cholecystenterostomy operated on for gall-stones by means of the anastomosis button, with seventeen recoveries, as against a mortality of thirty-five per cent., or eight deaths out of twenty-three cases operated on in one sitting, all by means of suture.

In performing cholecystenterostomy by the aid of this button I shall quote the various steps of the operation as described by the author:

"The button is inserted in the following manner: An incision is made from the edge of the rib two inches to the right of and parallel

geons in this country, the usefulness of this button, or the principle on which it operates, will not be limited alone to cholecystenterostomy, where it is already conceded to be the most practical device for the rapid performance of this difficult operation, but it will also find a field in end-to-end anastomoses, gastrostomies, gastroenterostomies, and the closure of faecal fistulae. As I have already remarked, the strongest argument in favor of its introduction should be the fact that such long and tedious operations are rendered easy, quick of execution, and comparatively safe. There is no question that it finds its most useful field in the formation of biliary fistulae, either external or into the bowel, since, having only fluid contents

to the median line, extending downward three inches. The gall-bladder is drawn into the wound, also the duodenum. The duodenum is cleared of its contents by gentle pressure with the fingers. My short intestinal compression forceps are placed upon the duodenum, to prevent the escape of gas and fluids after the incision is made. A needle with fifteen inches of silk thread is inserted in the duodenum, directly opposite the mesentery and at a point near the head of the pancreas. A stitch is taken through the entire wall of the bowel one-third the length of the incision to be made. The needle is again inserted one-third the length of the incision from its outlet, in a line with the first, and brought out again, embracing the same

amount of tissue as the first. A loop three inches long is held here and the needle is inserted in a similar manner, making two stitches parallel to the first in the reverse direction, and one-eighth of an inch from it, coming out at a point near the original insertion of the needle. This forms a running thread, which, when tightened, draws the incised edge of the bowel within the cup of the button. In the gall-bladder a similar running thread is inserted. An incision is now made in the intestine, in length two-thirds of the diameter of the button used. The button (one part of it) is slipped in, the running string tightened, and the button held with the forceps. An incision of the same length is then made in the gall-bladder and between the rows of sutures. The button (the other part of it) is inserted in a similar manner and the running string tied. The forceps are removed and the button parts are held between the fingers and pressed together. A sufficient degree of pressure must be used to bring the serous surfaces of the gall-bladder and intestine firmly in contact and compress the tissues. The elastic pressure of the spring cup of the button produces a pressure atrophy of the tissues embraced within the cup and leaves an opening as large as the button, the button dropping into the bowel and being passed through the intestines."

The objections made by Senn and others to the Murphy button in gastroenterostomy and lateral anastomosis, as allowing of too small an opening in such operations, led me to devise these instead, which I bring before you to-night.

They operate on the principle of the Murphy button, but can be made of any desired shape or size. The approximating power is furnished by rubber bands. These long, oval plates would leave an opening three inches in length. Rubber bands will remain in contact with the gastric juices for several days without undergoing any material change, and will retain, so far as I have been able to determine, their elasticity.

I show you to-night samples made from ivory, walrus tusks, horn, bone, and hard rubber. If, instead of being hollow and sharp, the edges of the button be cut flat and the bone partly decalcified, they can be used on the principle of the Senn plates, as splints, without requiring sutures to keep the serous coats in contact.

I shall shortly perform a number of gastroenterostomies on dogs, using these long, oval plates, and report within six months or so the results of the operations and the amount of contraction which has taken place in each case.

MEDIA, PA., January 24, 1894.

## A NEW DRESSING FOR CIRCUMCISION.

BY F. GUNDRUM, M.D., ESCUNDIDO, CAL.

ALL those members of our profession who have performed the operation of circumcision no doubt have had an experience similar to mine,—viz., that the most troublesome and trying time for both patient and surgeon comes after the operation. From the time of the first dressing until complete cicatrization has taken place—sometimes a period of weeks—there is more or less constant suffering, at least in the majority of cases. Too well do I remember how the little patients dreaded to have their wound dressed. In rarer cases, where there was a non-adherent prepuce, and where the wound healed by first intention, things progressed more favorably. But for those surgeons who believe, as I do, in tearing down the frænum, there is always more or less pain referred to this spot. Under the common dressing it necessarily follows that there must be more or less irritation, inflammation, and pain. Not alone is this due to the wound the surgeon makes, but it arises from the tender glans surface which has been exposed and often largely denuded of its epithelial covering in peeling the adherent prepuce from it.

Even if there have been no adhesions, a few days' exposure to the air, supplemented by irritating dressings, and last, but not least, the almost constant contact of urine, soon destroy the surface epithelium, thus depriving the acutely sensitive nerve-endings of their normal covering.

After removing the skin as far back as the sulcus or cervix of the penis, I make a dorsal incision through the mucous layer of the prepuce and entirely free the head, tearing down the frænum. I now trim off the mucous layer, leaving a sufficient width to turn back like a cuff and to be stitched to the skin.

This stitching is a very important part of the operation. It should be so neatly done that all raw surfaces are coaptated. The best material for suture is fine catgut. If this is not at hand, fine aseptic silk will do. Having completed this part of the operation, the penis should be thoroughly cleansed with some aseptic solution and completely dried. Now, with a camel's-hair brush, the penis is painted from the meatus almost to the root with the following mixture:

R. Resin, ʒii;  
Copal varnish, ʒii;  
Beeswax, ʒi;  
Tallow, ʒii;  
Iodoform, ʒi. M.

Heat to about 150° to 175° F.; stir, mixing the iodoform thoroughly. Allow to cool to 115° to 120° F., when it will be ready for use. Apply one coat, and allow it to harden; then another and another, until the penis is hermetically sealed, leaving the meatus free. The dressing is completed by wrapping one or two layers of aseptic gauze round the penis and painting with the mixture. The patient should be seen in forty-eight hours. If the bandage is loose, it should be removed. Two or three fresh coatings with the mixture should be applied. Of course the penis should be properly protected by a ring of cotton. The mother is instructed to warm the mixture and apply it with the brush daily until complete cicatrization has taken place. The precaution of testing the heat of the mixture by the finger should always be taken before applying it to the child. When this dressing is used there is no inflammation, no discharge, no swelling, no pain, and no crying and screaming.

Before using this dressing, the most troublesome feature of circumcision in children was the care of the patient after the operation. Now this is all changed. After the first night the patients seldom lose sleep and they eat well. This dressing fulfils all the indications. It is aseptic-antiseptic, and completely excludes air and all germ-life. Moreover, it keeps the urine from the wound and from raw or sensitive surfaces.

#### *THE CASES SUITABLE FOR EXCISION OF THE DRUMHEAD AND OSSICLES.*

By B. ALEX. RANDALL, M.A., M.D.,

Professor of Otology in the University of Pennsylvania and the Philadelphia Polyclinic, etc.

**T**HERE is much still very unsatisfactory in the treatment of chronic ear-diseases, limiting at once the certainty, rapidity, and completeness of success, and leaving much too large a proportion of cases in which the usual methods fail of cure, at least within what the patient regards as a reasonable time. This poor showing of Otology is not nearly so common as is often supposed, for the proportion and degree of successes compare favorably with that in most fields of medical practice. But the tradition which sets down the majority of chronic ear-troubles as incurable still prevails even among aurists, and will be long in receiving its merited death-blow. Until it is corrected, this impression, that the usual otological measures are inadequate, is likely to render a considerable part of the public, medical as well as lay, impatient of according any sufficient trial

to the well-proved means of treatment, and will lead them to hail with enthusiastic hope any new claims that make a plausible showing.

Especially does this hold true for operative intervention, which is in accord with the spirit of the time and is new enough to the general knowledge to have the charm of novelty undashed by acquaintance with numerous disappointments. Hence there is much inquiry among general practitioners as to the value of such a measure as excision of the drumhead and ossicles, which has been proclaimed as "the modern treatment for suppuration, deafness, and vertigo." The younger aurists are stimulated to make premature and ill-judged experiments with the methods, to overrate their value and safety, and to scorn the conservative attitude of elder aurists as timid and fossilized. But they do so much to bring condemnation upon operative procedures by exaggerating their benefits, overstepping the proper limits in the selection of cases, and bringing occasional disaster upon their patients, that the elders are frequently confirmed in their scepticism, and feel moved to an utter denunciation of the whole field, without at all trying it themselves.

Yet there is surely a middle course, wiser from a scientific point of view, and more just to the patients who confide their present and future welfare to the aurist's care, trusting him to know and employ the best means for their relief. Prejudiced inaction and rash intervention are equally to be condemned; and it behooves us to make our best endeavor to differentiate carefully the cases to which the various methods are properly applicable, and to define, as far as we may, the true field and value of these operative procedures.

The indications for operation will always be variously read by different men. The skillful operator, accustomed to success, hesitates less to attack the doubtful cases than another, properly self-distrustful, does about operating in those in which the need is clear and urgent. He who in long series of cases generally regarded as obstinate or incurable has had fairly full success by non-operative methods looks askance at another who publishes a host of operative results, which suggests that operation alone has been tried. Much of this will continue even after we have secured more uniform and rational nomenclature, made better records, and compiled more reliable statistics of ear-diseases, although great help may be expected from reforms in these directions. Study and diagnosis must be more thorough and exact, pathological teaching must be sought from wider fields, and prognosis must be more con-

scientifically drawn from fuller knowledge of the possibilities of the case in hand.

As a contribution to this subject, it has seemed well to bring forward some observations and thoughts upon the pathological conditions with which the aurist has to deal, especially in chronic suppurative cases, and thus to endeavor to eliminate some errors and to make clearer the indications for operation.

Tympanic inflammation almost always occurs as an extension from the nares by way of the Eustachian tube; and its successful treatment generally entails the removal of the diseased conditions still lurking in the nasal and tubal mucous membrane. Inflation from this side is usually an important diagnostic and therapeutic measure, and it must not be neglected in favor of means employed through the external auditory canal. Drainage to no inconsiderable amount habitually goes on through the tube, as the effete cells of the tympanum melt down into mucus and are swept away; and free passage in this direction must be assured, if we are wholly to terminate discharge outward. This should go without saying; yet in fact it has to my knowledge been frequently overlooked in cases where excision has been advised with no study of the patulency of the Eustachian tube and similar fundamental factors of health.

In the non-suppurative cases of catarrhal deafness there is no criterion by which to clearly recognize those for which excision is advisable. Instances of impaired bone conduction are almost sure to disappoint, and these must be excluded by tests with low- as well as high-pitched forks. Gelle's tests may indicate ankylosis of the stapes and direct any intervention to it rather than to the drumhead and larger ossicles. Urgent demand for relief may be enforced by marked aural vertigo or maddening tinnitus; but this will be very rarely the result of the tympanic catarrh. Serious vertigo of tympanic origin is uncommon even in the cicatricial cases which result from destructive suppuration. So, too, as to the tinnitus; it is often unimproved by excision, not rarely caused or increased by it. In only a small group of patients, impossible to designate beforehand, will the removal of the drum-membrane and larger ossicles give any noteworthy improvement which does not sink to the vanishing-point within a year or two. Schwartz, the pioneer in this field, has operated in rare instances since 1873 without getting any success that he has cared to publish, although regarding excision as "not contra-indicated." Lucae, who had done more than

forty excisions in 1881, concluded from his fifty-three cases, with notable gain in nine, slight gain in nineteen, and loss in seven, that operation was too uncertain, and has abandoned it. Dench made a notable gain in six, and slight improvement in four of his ten very carefully selected cases; but total loss of hearing has been reported by Kessel, Schwartz, and Wuerdeman, and few operators of wide experience have escaped results little less disastrous. Tinnitus has often been wholly unrelieved; and some patients, having looked to the operation as a sure last resort, have committed suicide as soon as its failure was apparent. Excision in carefully selected instances of catarrhal deafness may be expected to aid a considerable percentage of cases, but every patient must run a decided risk of failure, perhaps disastrous.

As to tympanic suppuration, accessibility is the prime necessity to its successful treatment. The lack of this when the attic and antrum are fully involved is the cause of the obstinacy of many otorrhœas which defy, perhaps, the most thorough employment of non-operative methods and furnish a real demand for surgical intervention. A high-placed perforation is often cited as constituting a poor means of drainage or of access,—a claim justified only in the cases where there is graver meaning in the location of the opening than has always been recognized. Perforations up and back, close below the posterior fold, frequently indicate caries of the incus-shank or of the adjacent tympanic margin. In like manner, as is better known, the openings in the flaccid membrane of Shrapnell point to foci of suppuration in the circumscribed upper cavities of the tympanum, where drainage is very imperfect, the entrance of medicinal means difficult, and the bone surfaces of the Rivinian margin and the malleus-neck especially liable to ulcerate. Caries, then, is the frequent reason for the intractability of the case, as it is also the reason for the high position of the perforation; and the question of operation, beyond the mere enlargement of narrow openings, hangs largely upon the presence and curability of carious conditions.

Brought about commonly by the retention of decomposing discharges, caries can hardly be combated unless this can be fully removed and reaccumulation prevented. Decayed bony spicules must be dislodged, and the granulations, which are nature's means of effecting the cure, must be destroyed when polypoid, and stimulated to healthy growth as soon as possible. Free access must be gained, and when

the presence of the ossicles proves an insuperable obstacle to this, their removal is clearly indicated. Yet experience has shown that drainage is sometimes no better after such an operation, that the carious surfaces are not upon the malleus and incus, or not there only, and that fuller intervention in the curetting of the walls of the attic, or the removal of the whole *scute*, so as to open the attic fully into the canal, is needful to establish full access. Moreover, there are not a few cases where the major lesion is in the antrum, and no amount of intervention which does not open it freely into the canal or outward upon the mastoid surface can give rational prospect of cure.

It is no reproach to otology to acknowledge, that the differentiation of these conditions is rarely possible beforehand, and that here, as in most other fields of surgery, the operation must be exploratory. An operation within the canal will always seem less severe and sweeping than a mastoid trephining or the procedure of Stacke, with its free cutting of the soft parts; just as patients and surgeons are apt to regard any amount of groping after a foreign body within the canal or tympanum which makes no external wound as a less serious matter than turning forward the dissected-up auricle and canal and doing the needful work in plain sight and within easy reach. Yet there will be a reduced mortality as well as other great gains when the latter operation obtains its proper place in aural surgery; and it is probable that the same is true as to excision of the ossicles.

The latter operation seems too easy to those who have not often assayed it, and know it only through the descriptions of its advocates; for there are few operators but have spent an hour or more over some of their first cases, and have failed even then to remove the incus. Perfected instruments and improved technique will lessen but never remove these difficulties, but they are doing much to render the simple excision a safe exploratory step in the cases demanding intervention. In but a portion of the cases proper for its employment will it prove more than this, and the aurist who holds it out as offering more frequent cure will disappoint himself and his patient. That statistics to the disproof of this can be readily cited does not at all controvert this claim, for analysis of the reported operations shows many points in which a strong presumption lies against the asserted showing. The experience of some operators is too small for their few favorable cases to count for much in such a broad question; that of others is suspiciously large. The following of cases to learn the final result has

been generally inadequate, the estimate of success sometimes contains too peculiar a personal equation, and the conclusions drawn and urged are at times at clear variance with the recorded facts. Taking the face-value of four hundred reported operations, we find a claimed success of sixty-five per cent., a result which sinks, for Americans and foreigners alike, to near fifty per cent. when the phenomenal and really incredible success of one operator in ninety-three per cent. of his eighty-four cases is left out of the count. Nearly half of the operations in cases selected as suitable for simple excision have thus far failed,—not such a bad showing, could we accept the view that these patients really required the operation, and that the ultimate results were as stated. Yet a glance at the published reports shows that many of these cases were not only lost sight of long before the apparent cure could be accepted as assured, but were also often operated on at once without trial of the less serious measures, which might have proved equal in efficacy.

It has been sagely claimed that if the caries be limited to the ossicles, their removal must end the disease. Experience has strengthened this claim, but it is far from full establishment, since the suppuration, with its imaginary and real dangers, can persist without bone lesion. The counter-claim, that caries can frequently be healed without resort to excision, is as well established by experience. Amputation of the leg is a fairly sure cure for in-growing toe-nail or tibial caries, but the surgeon rarely deems these measures called for, at least until more local means have been tried. It has been urged that the conservative healing of tympanic caries is apparent only; that after excision is real. Time, the only touchstone on which they can be tried, has rarely given a decisive test of the rival claims; and isolated results here and there support each side of the contention. That in dealing with at least two hundred instances of Shrapnell perforation and an equal number of other cases where caries of the ossicles was or seemed to be present I have operated by excision in only fifteen, may mark me as a timid surgeon; and I am free to say that a larger number, perhaps thrice as many, should have had radical measures. Many of these patients received and rejected the advice; many more were lost sight of before it could be fairly decided on. But only one-third of the operated cases were cured, and that only tardily, none too certainly, and apparently as much by other measures as by the excision. Not a single brilliant result has been met. On the other hand, quite one-third of the non-operated

patients were discharged with apparent cure as promptly achieved and often verified by years of subsequent observation. Nor should it be left out of consideration that not a few of these latter patients had already consulted capable men, advocates of excision, and been assured, after treatment or without it, that operation alone gave them any promise of cure.

Two recent cases in point may be cited. One had a perforation up and back (Fig. 2), fringed with granulations about bare bone on the tympanic margin and filled by a polyp arising from the incus-shank. The hearing was very poor, and operation was insisted on as the sole resort, although treatment had not been tried for some time, nor by a specialist. Biting off the polyp in studying the case restored the hearing for a faint whisper; rubbing and cauterizing the carious surfaces gave apparent cure in three weeks, with a good movable cicatrix closing the perforation. Slight relapse has occurred, and cure may be only seemingly gained after three months; but it has stood the test of severe coryzas, and the hearing has remained perfect. Another patient was offered excision for her growing catarrhal deafness. I found a flaccid membrane so distended by cholesteatoma as to hide the rest of the drumhead (Fig. 4). I restored the hearing to an excellently useful point by removing the collected material, and in two months secured a covering-in of the bare surfaces on the malleus and Rivinian margin that gives promise of permanency. Both cases are too recent to prove anything as to the ultimate issue, although each has been followed longer than many of the reported cures by excision; each has another important lesson to teach. The first had long since suffered a like lesion on the right side, and for a year past has had entire healing. Through the scar up and back in this membrane (Fig. 1) the stapes can be seen to be almost wholly disconnected from the incus, which seems to have lost its articular tip. Yet this serious lesion has healed, and the hearing is perfect. In the other case the right ear (Fig. 3) presents a puckered scar of the upper back quadrant, largely adherent to the inner wall and barely revealing the stapes which it enfolds. No trace of the incus is visible; its shank at least has been lost. Healing with grave loss of hearing has been present ten or more years; but gentle manipulation with probe and pneumatic speculum has so far mobilized the stapes that a loud whisper can be heard at six feet, and ordinary conversation at ten.

Another case has been under observation

three years or more at the Polyclinic. Both ears presented suppuration in the attic, with rough, bare bone and loss in the Rivinian segment, a seemingly carious area on each malleus-neck, and a perforation high up posteriorly with a granulation-covered margin, within which rough bone was felt. On the left side (Fig. 6) healing was secured with fair promptness, which has persisted, after an early relapse, for upward of two years. On the right (Fig. 5) the caries above the short process was more obstinate, and has repeatedly relapsed after apparent cure; it has now been quiescent about a year, and its cessation is growing more assured. The posterior perforation, however, has never closed nor been dry more than four months. I have repeatedly decided to operate, and as often have been led to stay my hand because of immediate improvement. Operation is probably necessary, but I doubt if the patient will consent.

Little idea of the curability of these conditions of caries can be gained from such citation of individual cases; and as to the majority of such patients I can make no report of verification of the cure after years. Some have no recognized trouble; but I impeach subjective evidence as inadequate to prove the reality of cure. Yet that carious conditions can thoroughly heal, testimony as competent as any that can be adduced may be obtained daily in our clinical work. Patients are often seen whose suppurative disease has been so long past as to have escaped or antedated recollection; yet examination shows clearly the ravages of caries above the short process or in the stapes-region. The neck and head of the malleus are exposed or partially destroyed (Fig. 7), or, the incus-shank having been lost, the stapes is freely open to view (Fig. 8). Sometimes the history is fairly clear as to the date and duration of the affection; whether so or not, the cure is indisputably complete, sometimes with perfect preservation of function.

The proof is conclusive that these cases of suppuration with carious lesions are not rarely curable without excision; and the hearing can be perfectly preserved or restored at times if impaired. The question turns, then, upon the safety and rapidity with which the results can be obtained in general and in the individual patients. No sufficient evidence can be as yet adduced on this point. My fifteen cases with no single prompt healing may be regarded as excessively severe tests of the measure; they certainly were not easy cases where other means had not been fairly tried, as the material of other operators has none too rarely been. They

1.

2.

3.

Right drumhead, with retraction and chalk deposit; foramen above the short process and circling backward, revealing the stapes and displaced incus.

4.

Left drumhead of the same patient, showing perforation up and back, with granular margins and protruding polyp.

5.

Right drumhead, showing old complicated scar investing the stapes; foramen above the short process.

6.

Left drumhead of the same patient, nearly concealed by the distended flaccid membrane from an opening in which the epidermal contents protrude.

7.

Right drumhead, with loss of the bony margin and uncovering of the malleus above short process; a perforation up and back shows only its prominent margin.

Left drumhead of same patient, healed for two years after suppuration and caries in the Rivinian region and near the stapes.

Right drumhead, showing loss of substance, laying open the attic and antrum and showing remains of the ossicles now healed.

Left ear of the same patient, with more extensive chalk deposit, less loss above the short process, but the stapes uncovered by absence of the incus.

were fair cases for the test, as they gave no evidence of extensive lesions, such as have led me to exclude six or eight other excisions from consideration here. On the other hand, I have no hesitation in impeaching many of the claimed successes as having been obtained in patients on whom the operation was not clearly necessary, or as having been followed too short a time to justify any statement as to definite cure. It has been the reproach of the non-operative methods that relapses occur, and a year of healing may not exclude recurrence. I claim that any one aurist of good experience can, like me, match an observed and verified case of unoperated caries healed for years against every operated one so cited by the advocates of excision. This does not ignore the fact that most of the men who have operated rarely have kept track of their cases, and that Ludwig and Gruenert have followed up the long series of Schwartz's patients.

As to the rapidity of cure, it may be appropriate to note that I have several times operated on one ear when the other was similar, sometimes apparently better, except in hearing, and have obtained a cure only long after the other ear was healed. The prompt cessation of discharge in some of the operative experience of others immediately after the removal of ossicles extensively carious, makes a showing for excision in appropriate cases which no scepticism can undervalue, especially when the gain has proved permanent. Yet milder measures have given as striking cures. Much in this relation must depend upon the skill and thoroughness with which milder measures are applied. Intra-tympanic syringing must often fail in whole or part when attempted with the clumsy canulas offered and figured. Skillful employment of the probe, with full penetration into the affected regions and removal of polyp-masses, epithelial collections, and pus, is a prime requisite to the study, as well as the treatment, of the patient; and he who cannot or will not do this has no right to ascribe his shortcomings to the method. Only when this has been conscientiously but vainly done for weeks or months is excision generally justifiable; and thus employed, simple excision will often prove as inadequate as I have generally found it.

Finally, as to the safety of excision. Disaster is rare, either from the operation or the anæsthesia. General narcosis is usually needed in the suppurative cases, and its possibilities of evil cannot be wholly ignored. Schwartz expects a loss of hearing in one-twelfth of his patients, which he offsets with gain in one-half. I have never improved the hearing by

operation, and I believe its influence largely negative where proper previous treatment has been given. The cases above cited show how the function may be bettered without resort to excision, and much has probably been ascribed to it with no justification. Facial paralysis has befallen some patients; my only case was tubercular, and supervened only a fortnight after operation. It may have been due to instillation of two-per-cent. nitric acid, which has several times been followed by bad results in my experience. The stapes has at times been unintentionally dislodged or removed, with no damage as yet reported. The operation will generally prove harmless, only disappointing; but we must expect occasional disaster.

The cases suitable for excision form a small group, including very few catarrhal cases, and only some of the really obstinate suppurations. Most of the serious purulent affections demand more radical intervention, of which this may form one step.

*THE INFLUENCE OF PIPERAZIN ON THE  
URINE, AND ESPECIALLY ON URIC-  
ACID AND UREA EXCRETION.  
UNTOWARD EFFECT OF  
LARGE DOSES OF  
THE DRUG.*

BY D. D. STEWART, M.D.,

Clinical Lecturer on Medicine in the Jefferson Medical College.

IN a previous paper on piperazin\* the results of a study of the drug on the urine in three cases of nephro-lithiasis was given. It was there remarked that though a cure resulted in two of these cases (of presumable uric-acid calculi) during the course of the piperazin treatment, no coincident noticeable influence was apparent on uric-acid excretion. The two cases cured were from their nature such as seemed insusceptible of relief by other than operative means. Striking amelioration, and subsequent cure, in the first of these cases, one of calculous hydronephrosis, had been too prompt after failure of other tried remedies to leave reasonable doubt as to cause, whatever ambiguity might exist as to the *modus operandi* of the remedy. In the second case, also, one of suppurating kidney, with frequent attacks of renal colic and hæmaturia, of seven years' duration, symptoms finally disappeared after taking piperazin steadily for three months.†

\* THERAPEUTIC GAZETTE, January, 1893.

† These cases, followed to the present, have remained cured. Case I., in which the passage of gravel was of almost daily occurrence, has passed none since. She resorts to piperazin on the occasional reappearance of slight

The third case was probably one of calcium oxalate stone, which, from its composition, had not been thought susceptible of solution by piperazin; in this case no benefit followed its administration.

In these three cases uric-acid excretion was habitually abnormally high, notably in Case II., and the daily fluctuations were often extensive. It was not apparent, however, that excretion of either uric acid or of urea, or even the degree of acidity of the urine, were markedly influenced by the piperazin in the doses administered, the average of which was a half-drachm daily, double that previously used by most observers. Notwithstanding a considerable range in the daily fluctuations of uric acid in the three cases, the average of several days' estimate of amount prior to taking piperazin and while under its influence was practically very similar. It therefore seemed curious to understand the mode of action of piperazin from the stand-point of influence upon uric-acid excretion. As I remarked in the former paper on piperazin, a uric-acid calculus may be of no very small size and yet undergo moderately prompt solution without the fact being detected by quantitative examination of the urine, the light weight of the stone not appreciably affecting the continuous daily variations in excretion. Yet, from the supposed action of piperazin, combining with and forming a soluble salt of uric acid, it was *a priori* supposed that some increase in uric-acid excretion would be apparent. The bulk of the evidence, however, at the time of the appearance of my paper, was, curiously, to the effect that piperazin, though it had, *in vitro*, a markedly disintegrating effect on uric acid, with which it forms the most soluble salt of the latter known, does not actually, in the doses ordinarily advised, increase uratic excretion, however much benefit it seems to exert on cases the nature of which are dependent upon impairment of the latter.

I have myself also obtained at least apparent good results with piperazin in certain other cases of gravel, in one other of suspected renal calculus,—the only other case of stone in the kidney that I have encountered since first using the drug,—and in a case of monarthritic subacute enlargement of the wrist-joint of supposed gouty origin. In the last a decided diminution in the joint swelling occurred under the influence of piperazin, in doses of but 15 grains daily, and pain, which pre-

viously had been severe, also promptly disappeared. In several of these cases some increase in the amount of urine under piperazin was noted. These results naturally gave me some confidence in piperazin, and I have been curious to discover its probable mode of operating, and to determine by further experiment if it is in all cases without influence on uric-acid excretion. As the cases before reported in which quantitative uric-acid examinations were made were those with kidneys the function of one or both of which would be somewhat disturbed by the presence of stone, it was important to repeat them in cases other than these, employing it both in moderate and in large doses.

In the following case piperazin was tried in moderate doses for a short time to determine its influence in stimulating inadequate kidneys. The case is one of chronic Bright's disease, in which, with the constant presence of mild uræmic symptoms, albumin remains absent from the urine. The latter, however, contains casts, and there is persistent decided diminution in the excretion of urinary solids, notably urea. Uric acid is excreted in what may be considered normal amount, though it is also presumed to be present in excess in the blood.\* In this case, besides many odd examinations, twenty-two daily consecutive examinations of specimens of the twenty-four hour urine were made for the purpose of ascertaining the actual working condition of the kidney over some time. The specific gravity, degree of acidity, amount of uric acid, urea, and chlorides excreted were carefully noted. The patient, himself an analytical chemist, was careful to live very regularly as to diet and exercise during this time. At the middle of the period of this examination piperazin was administered for six consecutive days, in doses of 5 grains four times daily.

In the twenty-two days the daily average amount of urine passed was 1085 cubic centimetres (36 fluidounces). The daily average amount of urea was 18.56 grammes; of uric acid was 0.713 gramme; of chlorides, calculated as chlorine, 4.82 grammes. The approximate daily average amount of total urinary solids was 43 grammes.

The following table, copied from my paper on non-albuminuric Bright's disease, just referred to, gives the consecutive daily amounts of urine, specific gravity, acidity, uric acid, urea, and chlorides before taking and while on piperazin:

loin pains, and always with a successful result as regards disappearance of symptoms. These pains, long prior to the appearance of symptoms of stone, were premonitory of the onset of fits of gravel.

\*A history of this case is published in the *American Journal of the Medical Sciences*, December, 1893, in a paper on a non-albuminuric form of Bright's disease.

## CASE OF W. B.

Date.	Daily average amount of urine in cubic centimetres.	Specific gravity of mixed 24-hour specimen.	Degree of acidity calculated on 100 cubic centimetres of urine.	Daily elimination of urea in grammes.	Daily elimination of uric acid in grammes.	Daily elimination of chlorine in grammes.	Approximate daily amount of fluid taken.	Remarks.
Jan. 31, 1893.....	1740	1013	7	22.70	.764	Not estimated.	Over 4 pints.	Meat diet throughout the 23 days.
Feb. 1, 1893.....	1650	1014	11	18.00	.329	Not estimated.	Over 4 pints.	
Feb. 2, 1893.....	1400	1015	18	20.00	.950	Not estimated.	Over 4 pints.

20 grains of piperazin taken daily from the 11th to the 17th.

During the six days in which piperazin was taken the average amount of urine passed was 1200 cubic centimetres (40 ounces); the average excretion of uric acid was .831 gramme; that of urea was 19.9 grammes; and of chlorine, 4.58 grammes. The approximate average of total urinary solids was 46 grammes (730 grains). During the six days in which piperazin was taken the average amount of urine passed was 915 cubic centimetres (30 1/2 ounces). The average excretion of uric acid was .699 gramme, and that of urea was 18.34 grammes, and chlorine 4.31 grammes. The approximate average amount of total urinary solids was 39 3/3 grammes (610 grains). It may be thus seen that actually a slight diminution occurred not only in the amount of urine, but in the most important of the urinary constituents, notably uric acid and urea. The difference is, however, too slight to be explained by any influence exerted by piperazin on the kidney. I have found that in most cases, if any effect at all is obtained from piperazin, at least a slight increase in the amount of urine passed may be expected. In this case the kidneys were probably too inadequate from disease to respond to the stimulating effect of piperazin. Though placed under the most favorable conditions,

the patient recently reports that the amount of urine habitually passed has diminished to 500 cubic centimetres, with a corresponding increase in the symptoms of chronic uræmic intoxication.

Hitherto no observations as to the effect of large doses of piperazin on the urine, such as a drachm or more daily, have been published. Whether such doses could be borne without injury and better results obtained by them, seemed a point well worth determining. It had seemed to me that only in such amounts could benefit be expected, if any was to be obtained, in cases of chronic multiple arthritic enlargement of presumable uratic origin. This is, of course, on the supposition that piperazin has some influence in promoting the solution and excretion of retained insoluble urates. In the following case the indications are that the chronic arthritis is of gouty origin and due to the deposit of urates in the joints through imperfect excretion on account of inadequate kidneys. It therefore seemed a particularly appropriate case for determining the effects of large doses of piperazin.

The patient is Mrs. J. K. M., aged fifty-two; weight, one hundred and fifty pounds. She came under observation in May, 1892, having been

kindly referred to me by Professor Keen for treatment. The joint-trouble began about a year before. The left knee then became swollen, and in the following October the right knee. She had never at any time previously had even a slight attack of rheumatism, nor had there been an outbreak of acute gout. There is no family history of gout or rheumatism. When first seen the knees were only slightly swollen, the left more especially so, and towards the inner surface. Much pain was felt in the joints, especially on movement. There was, besides, a steady, slighter pain always present. A distinct creaking was produced about the patella in extending and flexing the knees. Several of the interphalangeal joints of both hands were at times very painful. Two or three of these showed a tendency to slight nodular enlargement, and there was a nodular swelling on the dorsal surface of the left hand. There was no tendency towards spindling of the enlarged joints, when present so characteristic of rheumatoid arthritis. In addition to the pains felt on locomotion and the slight, steady pain in the knees, attacks of pain, at times quite severe, occurred. These were felt about the knees, in the nucha, and in the finger-joints, and at times were often shooting in character. These always corresponded in onset with a diminution in the excretion of uric acid, as is narrated below. The patient still menstruated, was well nourished, and though there was total gastric acidity (which still exists), she complained but little of symptoms of indigestion. When she first came under observation the stools were pipe-clay colored, but subsequently, under lavage, they gradually resumed their natural hue. The arterial tension is habitually raised, the sphygmogram always showing the elevated, rounded tidal wave of increased blood-pressure, with the chief descending wave higher than normal, the tracing of raised blood-pressure characteristic, when associated with certain other symptoms, of granular kidneys. There is no discernible arterial thickening nor cardiac hypertrophy. The first sound is, however, very distinct and the second accentuated at the apex. The last is normally placed.

While the patient was under Dr. Keen's care she had taken 15 grains of piperazin daily for seven weeks. This was before I saw her. This had been absolutely without effect upon the joint-trouble, though the amount of urine was quite markedly increased by it. The daily amount of urine prior to resorting to piperazin had averaged but 900 to 1015 cubic centimetres. Under the daily doses of 15 grains it ran between

1200 to 1800 cubic centimetres. From May, 1892, to the present I have made frequent examinations of the urine, the daily output being often measured for several consecutive months, with not infrequently consecutive daily estimations of uric acid and of urea for several weeks running. Thus a very good idea has been obtained of the usual urinary condition, uninfluenced by drugs, as well as of the effects of certain medicaments upon the kidney. The average daily amount of urine passed during the first five months, at intervals when no drugs were taken, was, as is stated above, with an average specific gravity of 1010. Recently, though the volume is subject often to wide variations, the amount, uninfluenced by drugs, tends to be somewhat excessive, and of very pale color and low gravity, resembling the urine of a case of fibroid kidney, the probable renal condition present. Urea is habitually low, averaging 18 grammes (270 grains) daily. The amount for her weight should be in the vicinity of 30 grammes, on average diet. When no acute attacks of pain about the joints occur, the average daily uric-acid excretion is 0.5 gramme. The acute joint pain is usually characterized by a diminution in excretion, the amount often falling to 0.1 gramme or below, indicating at such times impaired solubility of the quadriurates in the blood, with a tendency to their deposition, as sodium biurate, about the cartilages and synovial tissues of the joints.

In this patient two forms of piperazin were tried. My former paper on piperazin was based on the use of the Schering product only, and all remarks heretofore made concerning piperazin in the cases cited apply solely to it. Recently another preparation of basic piperazin has been put upon the market,—that of Bayer's. A sample of this was placed in my hands for trial. I used this upon the patient under consideration, administering it in very full doses,—larger than have been before tried,—to determine the effect of these upon uratic excretion, and upon the joint swelling and pain. Because of the cost of Schering's piperazin I had not then been able to try it in very large doses. Later, however, Messrs. Lehn and Fink kindly placed a supply in my hands for comparison of effects with the piperazin of Bayer. It will be seen, as narrated later, that the untoward effects resulting with the very large doses used occurred with the Bayer product, which had been employed in the two cases. These untoward effects were noticeable only to a slight extent with the piperazin of Schering, used in the one case in about the same dose.

As the accompanying table demonstrates,

## CASE OF MRS. J. K. M.

Date.	Amount in cubic centimetres.	Amount in fluid drachms.	Color.	Specific gravity.	Degree of acidity calculated on 100 cubic centimetres.	Urea in grammes.			
April 5, 1893....	660	22	Yellow.	1020	20	14.50	0.230	2.50	The amount of fluid taken lay between 2 and 3 pints daily throughout the period in which these urine examinations were made. Joint pains severe.
April 6, 1893 ...	1380	46	Light yellow.	1018	25	25.00	1.000	6.00	
April 7, 1893....	1800	60	Very pale yellow.	1010	15	18.00	0.100	6.33	
April 8, 1893....	1980	66	Very pale yellow.	1009	6	19.80	0.134	6.00	Joint pains severe; 15 grains of Bayer's piperazin taken.
April 9, 1893....	1500	50	Very pale yellow.	1012	10	18.00	0.168	4.00	Joint pains less; 25 grains of Bayer's piperazin taken.
April 10, 1893....	1800	60	Very pale yellow.	1010	11	18.00	0.181	4.75	25 grains of Bayer's piperazin taken.
April 11, 1893....	1860	62	Very pale yellow.	1008	20	18.60	0.840	4.00	25 grains of Bayer's piperazin taken.
April 12, 1893....	1860	■	Very pale yellow.	1012	20	22.12	0.500	3.00	On the 12th 70 grains of Bayer's piperazin taken; untoward effects appeared towards end of day, after third dose; piperazin then discontinued.
April 13, 1893....	1080	36	Yellow.	1014	33	14.50	0.650	3.00

both preparations of piperazin were practically without other observable effect upon the urine than that they increased the quantity of that fluid. No influence whatever was apparent upon the constituent which it had been hoped most to reach. In this case observations prior to those tabulated, as has been stated, showed an average uric-acid excretion of 0.5 gramme, which latter figure, however, was often subject to considerable variation, depending largely upon the condition of the joints, whether subject to severe pain or not. A marked increase would often follow a decided diminution or the converse, as is apparent from the table, under dates of April 5, 6, and 7, and, again, on the 10th and 11th. No steady, detectable increase occurred as a result of steady, large doses of piperazin, such as 70 grains daily. Urea excretion, and that of chlorine also, remained unaltered, as had been anticipated, for no claims have been advanced as to any effect upon another constituent of the urine than uric acid. In this case piperazin invariably exerted a marked diuretic influence. When piperazin was rebegun, on May 14, the urine promptly rose from 1080 cubic centimetres to over 2000 cubic centimetres, and this increase was well maintained while piperazin was continued, as is usual. This increase in urinary water, apart from effect upon its contained ingredients, I have found is a common result of the use of the drug, although it is not noticeable in all cases. The urine in the case under consideration, as in that of all who take piperazin, underwent decomposition very early after voiding, soon becoming of an exceedingly fetid odor. Though its degree of acidity was lessened, an alkaline action was never apparent. Joint pains diminished considerably on the piperazin treatment, but subsequently returned almost as pronouncedly as before. No noticeable effect was apparent on the joint swelling from the use of piperazin.

[Since writing the above I have again used piperazin in this case, and with better results than before. On this occasion it was prescribed in combination with potassium citrate, which alone, in similar doses, had previously had no effect upon the symptoms. It had occurred to me that the contradictory results obtained with piperazin, and the lack of marked benefit in the case just recorded, might be explained by some difference in the degree of alkalinity of the blood in those taking the drug. In the gouty, with a tendency to joint implication, as in the case of J. K. M., the alkalinity of the blood and tissues is usually diminished. As a result it would appear, on consideration, practically impossible for a soluble salt of piperazin and uric acid to be formed from the urate deposited in the joints or with that in the blood, or, if formed, for this salt to effect a passage through the blood into the urine, unless an alkali were coincidentally administered. With this idea

in mind, a half-drachm of potassium citrate was given with each dose of piperazin. On this occasion piperazin chloride, made by Bayer, and furnished me by Messrs. Schieffelin, of New York, for experimentation, was used. Doses of 15 grains of this salt were administered four times daily for four days, and then 5-grain doses four times daily for six days. The large doses at first tried were used to note if any untoward effect could be produced by them. The result, as regards toxic action, was entirely negative. As regards influence on the symptoms, joint pains, which had been severe prior to taking the combination, ceased on the second day, and remained absent, with marked diminution in size of the affected joints at the end of ten days. There was no recurrence of pain until about two months later; then exposure in a rain-storm provoked a return of pains, which were again checked by the potash and piperazin. On this occasion Schering's piperazin, in doses of 5 grains, were used, instead of the piperazin chloride of Bayer,—the supply of the latter having become exhausted. The fact that potash alone, when used on a former occasion, was without any such effect upon the joint pain and swelling, indicates, in view of the lack of marked result with piperazin alone, that some virtue exists in this combination, and that the explanation lies in the direction just indicated. Of course, it may be that the symptoms might be benefited on one occasion by the potash, and on another not, though that seems unlikely. As the paper goes to press, a second trial in this case of, first, potassium citrate alone, and, again, potassium citrate, in the same dose, in combination with piperazin, gave results identical with the above. But little improvement occurred with the potash alone in joint pain and swelling, which had returned. Decided reduction in these symptoms were once more noticeable after taking the combination.]

The effects of piperazin in this case, in the doses used,—much larger than those hitherto resorted to,—taken in connection with the result of urine examinations by myself and by other observers, in many other cases in which piperazin has been administered, show quite conclusively that the drug is practically without effect upon uric-acid excretion, at least *uric acid as uric acid*. As a result, I confess I am at a loss to understand its mode of action, and were not my clinical results in most of the few cases in which I have used piperazin, other than in the case just recorded, as favorable as those of laboratory investigation were unpromising, I should certainly, on *a priori* grounds, unhesitatingly condemn the remedy as useless. As it is, I shall still employ it discriminately, at least so long as I obtain the desired effects, and that irrespective of mode of action. As regards the latter, I shall not look for a uric acid increase by its use.

There seems little doubt as to the admirable clinical results obtained in certain cases dependent upon the uric-acid condition, accounts of which, from trustworthy observers, have appeared frequently in Germany, though its

action is so obscure. Very recently a report of some experiments of Biesenthal tend to confirm further the good opinion reached based upon clinical data. Biesenthal induced artificially the deposit of uric acid and acid urates in the joints and tissues of doves by the well-known method of Ebstein,—that of gradual destruction of the renal-secreting structure by subcutaneous injections of neutral potassium chromate. To a large number of pigeons thus experimented upon, piperazin was coincidentally administered, with the object of noting if this drug would prevent the formation of these deposits. The results obtained were most interesting. In a very large percentage of the doves which received piperazin, it is stated that none of the characteristic deposits of urates occurred, indicating that piperazin actually possesses the power which test-tube experiments attribute to it.\*

So far as I can see, since piperazin does not increase uric-acid excretion, and apparently does exert a salutary effect upon the uric-acid condition, the only mode of action possible is that such as has been attributed to certain of the alkalies, such as vegetable acid salts of potash.\* The increased alkalinity of the blood these latter produce is supposed to promote its oxidation function, increasing the formation of urea, and, perhaps, also, transforming a modicum of the uric acid by oxidation into the former, or into a second more oxidized product than uric acid, such as bodies of the alloxan or allantoin series. Though no data is at hand showing that a transformation of uric acid into urea occurs in the organism, the fact that uric acid is so closely related to the latter, each molecule containing as it does the residue of two molecules of urea, and that uric acid may be so readily made to yield urea as a product of its oxidational decomposition; and, moreover, that when uric acid is administered by the mouth to mammals, considerable of it appears in the urine as urea, tends to indicate that such a metamorphosis may occur in the human organism under favorable condi-

tions. An investigation of the action of piperazin from this stand-point may throw light upon its action, otherwise so obscure. The urea formed from a portion of the uric acid would, of course, be in such small quantity as to be practically unrecognized by quantitative tests; because of the normal daily variation, a gramme or so increase would be susceptible of a varied explanation. The detection of the presence of allantoin or alloxan in any quantity in the urine under the use of piperazin could be more easily interpreted.

*Untoward Effects of Piperazin.*—To determine if piperazin could be given in large doses without toxic effects occurring, and also to note the influence of these doses upon uric-acid excretion, I administered both the Schering and the Bayer product in the amounts cited in the table in the case of Mrs. J. K. M. A marked difference was noted in the relative toxic effects of the two, but none in the action on uric-acid excretion, both being equally inactive in this direction.

Piperazin Bayer had been taken for five days; the first day 15 grains, the second, third, and fourth day 25 grains, and the fifth day 70 grains, when toxic symptoms ensued. These appeared after the third dose of 23 grains on the day on which 70 grains were taken. A feeling of nervousness and apprehension was first noticed early in the day, but was disregarded by the patient and the remedy continued. Shortly after the third dose of 23 grains on the day on which the 70 grains were taken, intermittent, clonic spasms of the upper extremities appeared, spreading to the muscles of the abdomen and legs, but manifest to a less degree there. The patient became dazed, was unable to think clearly, and seemed for some hours partly unconscious. This condition continued for about three hours, in the latter part of the time to a less degree. Associated with it there was muscular prostration with inco-ordination. The tremors were coarse, and became more intermittent and slighter, until they totally disappeared about thirty hours after their onset. Considerable uncertainty as to gait continued for several days, and seemed rather due to impairment of co-ordination than to any parietic condition of the muscles.

Much slighter untoward effects occurred from the piperazin of Schering in the same dose, and then only after it had been taken for a much longer period. Slight tremor in the hands and arms, with malaise and nausea, occurred on the seventh day. She had then taken 20 grains on the first day, 40 on the

\* It may not be improbable that a difference in the degree of alkalinity of the blood in birds and in man will be found to account for the striking results obtained with piperazin in these experiments,—results not accruing from its use in many cases in man. As is well known, birds and serpents excrete their nitrogen, not as urea but as uric acid. The alkalinity of the blood of the herbivora is greater than in man, but I am unaware of any observations as to this point made on the blood of birds. It seems likely, however, that a similar condition must obtain with the latter, in order that the passage of uric acid through the blood and its free excretion by the kidney may be readily accomplished.

second, 60 on the third, and 70 each on the fourth, fifth, sixth, and seventh days, as indicated in the table preceding. Piperazin was then discontinued, and the toxic symptoms disappeared. On the following day (the eighth) 25 grains additional of Schering's were taken; this dose was repeated on the ninth, and then 70 grains each were taken on the tenth and eleventh days, and 25 grains on the twelfth. The supply of piperazin then became exhausted. No recurrence of toxic effects was noted after the seventh day.

More marked toxic symptoms occurred in the following case under excessive doses of the basic piperazin of Bayer:

The case is that of J. MacK., aged fifty, a case in which there is an undoubted blending of both rheumatoid and rheumatic arthritis. The joints of the fingers, toes, wrists, shoulders, ankles, and knees were affected. The patient was somewhat cachectic. There was total gastric anacidity. The bowels were constipated; the appetite poor. Urine for four days preceding taking the piperazin ran: 870 cubic centimeters, 1000 cubic centimetres, 1260 cubic centimetres, and 900 cubic centimetres; specific gravity, 1021, 1025, 1021, 1025; urea, 14 grammes, 23 grammes, 16.34 grammes, and 20.20 grammes; uric acid, 0.36 gramme, 0.537 gramme, 0.574 gramme, and 0.544 gramme. During the two days in which piperazin was taken the figures were as follows: Amount, 885 cubic centimeters and 1200 cubic centimetres; specific gravity, 1028 and 1015; urea, 30 grammes and 20 grammes; uric acid, 0.620 and 0.645 gramme. Albumin was absent. 30 grains of piperazin were given the first day, and 70 grains the second, the patient being cautioned to discontinue the remedy on the appearance of any unpleasant symptoms, such as had occurred in the preceding case. He was an ignorant fellow, a dispensary case, and failed altogether to heed my admonitions. Notwithstanding the appearance of tremors, with muscular weakness and inco-ordination, at the end of the second day, after the third dose on that day of 23 grains, he took a similar-sized dose the following morning, though the tremors and jerking of the limbs had continued through the night, and he had been delirious and sleepless. Potassium bromide was prescribed in full doses, and would probably have controlled the nervous symptoms had not the attendants, in their ignorance and through their anxiety to relieve him, administered to him 2 to 3 ounces of whiskey through the day. He was already debilitated, had been on very low diet through poverty, and was

naturally, I was told, very susceptible to alcoholic stimulants. This probably accounted for the further conduct of the case. Towards night, the jerking in the limbs continuing, he had hallucinations, and became violent and abusive. The following day tremors and prostration had largely disappeared, but his mind was completely unbalanced. He wandered about aimlessly, and was violent if restraint was attempted. He had hallucinations and delusions, and was uncontrollable to such an extent that his people asked to have him committed to the insane department of the Philadelphia Hospital. After a detention there of a few days he returned to his normal condition.

The difference in the toxic dose of these two preparations of the basic piperazin is considerable. This, it may be supposed, is due to one of two reasons: either to greater concentration of drug in the one case,—i.e., less water of crystallization, the drug, however pure, being toxic in large dose,—or to the presence in the more toxic preparation of certain bi-products occurring in manufacture, these and not piperazin producing the effects noted. If the latter is the case, these exist in greater quantity in the piperazin of Bayer than in that of Schering. It is noteworthy that the piperazin of Schering also caused toxic symptoms, but only after it had been taken a much longer time and in greater amount. These symptoms, too, when occurring, were much less in degree and in duration than the untoward effects produced by the other basic preparation of the drug. Still, they did occur, and this indicates that the same toxic principle exists in both piperazins, though not to the same extent in equal amounts of the two drugs.

It is proper to state in conclusion that, communicating with the Farbenfabriken von Bayer u. Co. as to the cause of the difference in toxic effects of similar excessive doses of the two piperazins, I was informed that it was due to their piperazin being more concentrated,—that is, containing less water of crystallization than the other piperazin.

That there may be truth in this is shown by a recent statement of Wittzack (*Munch. Med. Woch.*, 28, 1893, quoted in the *Brit. Med. Journ.*, July 29, 1893), who, in remarking that the hygroscopic property of piperazin must be borne in mind, lest disappointment attend its use, states that some samples of piperazin were found to contain as much as fifty per cent. of water. For this reason he recommends salts of piperazin, rather than the base, as the more stable.

### GUAIACOL AS AN ANTIPYRETIC.

GUAIACOL has been used, as is well known, as a substitute for creosote in a large number of cases of pulmonary disease where that drug was indicated, and, so far as we know, has given so much satisfaction that it bids fair to supplant creosote in the treatment of many of these affections. Within the last few months the profession has begun to recognize the fact that it possesses other powers than those of an expectorant and antiseptic, or stimulant of the mucous membrane, and a number of prominent physicians have employed it for the reduction of high temperature.

Two of the most notable contributions which have been made upon this subject—the clinical lecture of J. M. Da Costa and the interesting paper of Robilliard—are particularly worthy of note. In both instances these clini-

cians used the drug externally upon the skin of the thigh, abdomen, or chest, either by means of rubbing or by painting it on with a camel's-hair brush. After it was applied to the skin it was thought advisable in some cases to place an impermeable dressing over it in order to prevent evaporation. As a result of the application of 20 to 50 minims of guaiacol in this manner, it has been found that the temperature of malarial fever, typhoid fever, and pneumonia rapidly falls as much as seven degrees in the course of an hour or two. Da Costa asserts that this rapid reduction of temperature is not accompanied by any marked disturbance of the nervous system or any evidences of collapse, not even by a very profuse sweat, neither does there appear to be a very active chill, although sometimes slight chilliness is experienced. The drug does not seem capable of holding the temperature down for any length of time, but it has been found perfectly safe to employ it as often in the twenty-four hours as is necessary to prevent pyrexia appearing with severity. Da Costa suggests that in many instances it may take the place of the cold bath, so far as the reduction of the fever is concerned; but whether or not guaiacol, on further use, proves to be a valuable antipyretic, we are sure that the therapeutic results obtained by the cold bath cannot be substituted by this means of treatment, since the cold bath undoubtedly exercises a therapeutic effect over and above that produced by guaiacol. We do not wish to be understood as stating that Dr. Da Costa believes that the cold bath should not be retained. He simply suggests that guaiacol be employed in its place when, because of the lack of attendants, the bath treatment cannot be well carried out, and because he believes that guaiacol is preferable to the antipyretics derived from coal-tar in the reduction of temperature. In the treatment of hectic fever of tuberculosis, J. Solis Cohen and others have found this drug of equal value. It may be painted over the chest in the area occupied by the pulmonary disease, but is said to be contraindicated in cases in which there are hemorrhages or well-developed cavities.

### A NEW TREATMENT OF MORPHINE-POISONING.

SOME of the readers of the THERAPEUTIC GAZETTE will probably remember the interesting contribution from the Laboratory of Therapeutics of the Jefferson Medical College, made by Dr. Thornton, in which he proved

that permanganate of potassium was the best chemical antidote we have for phosphorus-poisoning. Undoubtedly this influence of the permanganate is exercised through its powerful oxidizing properties, and at the time of his experiments Dr. Thornton proved to his own satisfaction that the permanganate possessed the power of oxidizing many of the vegetable alkaloids, notably morphine. Unfortunately, he did not continue his researches, and in consequence failed to report the results of his studies. In the last few weeks Dr. Moor, of New York, has demonstrated upon animals and upon himself that as much as 3 or 4 grains of the sulphate of morphine can be taken internally, provided a similar or double number of grains of permanganate of potassium are also swallowed at the same time or very shortly after. The results of these studies are of so much importance clinically, in view of the frequency of opium-poisoning, that we trust that further observations will confirm their accuracy, and it would seem that, both on theoretical and practical grounds, there is little doubt that this happy conclusion will be reached. Doubtless many studies will be made within the next few months, and clinical observations will be reported which will place this remedial measure upon a definite basis.

---

*AN ADDITIONAL NOTE ON SUBCONJUNCTIVAL INJECTIONS OF CORROSIVE SUBLIMATE.*

---

IN the issue of the THERAPEUTIC GAZETTE for June, 1893, we reviewed the literature concerning the treatment of various ocular diseases by means of subconjunctival injections of bichloride of mercury, and particularly the communications of Darier upon this method of therapeusis. The opinion then expressed was that this procedure should have wide and universal trial, because only by gathering together the views of unbiassed reporters, based upon large experience in widely diverse affections, could correct conclusions be reached as to its exact value.

Since the publication of this article much additional literature has accumulated, particularly the replies of numerous ophthalmic surgeons to the circular letter sent out by Valude, asking for expressions of opinion concerning the advantages, or otherwise, of this means of introducing mercury into the ocular tissues, a lengthy review of which appeared in the GAZETTE for December, 1893. Among twenty-five answers, fifteen surgeons were more or less

favorable to the use of the injections, six were opposed to their employment, and three objected to them on theoretical grounds. One surgeon gave evidence, and that unfavorable, only in regard to their efficacy against trachoma, and another, while he denied virtue to corrosive-sublimate, valued similar injections with trichloride of iodine. An instructive American communication was published in the last issue of the GAZETTE, and represented the experience with the method in the ophthalmic service of Jefferson Medical College Hospital. In this report cases of episcleritis and syphilitic and gonorrhoeal iritis were favorably impressed, cases of interstitial keratitis were either not improved or made worse, while cases of corneal ulcers were healed no more rapidly than by ordinary measures, or were aggravated by the treatment.

The theory of the treatment is evident,—namely, that a drug which is believed to be antagonistic to the morbid process shall be introduced directly into the affected organ, and thus come in contact in a concentrated form with the lesion which it is to antagonize. Whether this theory is compatible with facts it is at present impossible to decide, chiefly because we are not yet in possession of sufficient data to understand the fate of the medicinal constituent of the fluid when it comes in contact with tissues into which it is injected. That after penetration, fluids, and hence corrosive-sublimate lotion, find their way through the ocular coats, probably along the interstitial lymphatic lines, mingle with the humors of the eye, and directly bathe its cellular elements, seems undoubted; that certain drugs, thus introduced, particularly soluble salts of mercury, have a species of selective influence upon the uveal tract seems likely; but the exact relation of the physiological action of the medicament—chemical, bactericidal, or alterative—is not definitely known, on the one hand, for the reasons already quoted, and, on the other, because the feebleness of the dose renders it difficult to appreciate how action of any kind can take place.

The latter point is discussed by Lagrange (*Archives Cliniques de Bordeaux*, No. 12, 1893), who introduces some interesting calculations, which are appended. If 5 drops of 1 to 1000 solution of corrosive sublimate are injected beneath the conjunctiva, only about one-quarter of a milligramme of the drug finds entrance; but if iritis, for example, is treated with hypodermic injections of mercury or with mercurial inunctions, the doses are proportionately weak. For example, if for ten days there

is given a daily injection of 5 centigrammes of sublimate beneath the skin (a dose approaching a toxic influence, the usual one being 1 centigramme), fifty centigrammes would result during the time chosen, and these would be obliged to distribute themselves through the entire organism. That is to say, in ten days seventy kilogrammes of tissue (the average weight of the human body) will have absorbed fifty centigrammes of the liquid, and this only on the supposition that the entire amount would be present on the tenth day, when really a great proportion of it would have been eliminated. Now, fifty centigrammes distributed over seventy kilogrammes, gives less than one centigramme for each kilogramme; in exact numbers .0071. Fifty grammes of tissue have evidently received twenty times less sublimate than one kilogramme,—i.e., about three-tenths of a milligramme (in exact numbers .000355). But the eye weighs only eight grammes, and, adding the surrounding soft parts,—orbit and eyelids,—the entire weight does not amount to fifty grammes. If 5 drops of sublimate lotion (1 to 1000) are injected at one time, one-quarter of a milligramme of the drug is at once introduced into the eye and its surrounding parts, while if fifty centigrammes of sublimate lotion are given hypodermically during ten days (and more cannot be safely employed), only about one-third of a milligramme of the drug is introduced into the eye and orbit during the whole period. Lagrange regards this calculation as suggestive, and thinks it should convince those who have doubts as to the rationality of the procedure.

It is unnecessary to point out one or two evident fallacies in this endeavor to apply mathematics to therapeutic influences, particularly in the assumption as to the division and distribution of the drug; but if it is conceded that it helps to answer objections as to the smallness of the doses employed, it still leaves unanswered the remaining and probably most important point,—viz., the exact chemical relation of the medicament to that of the fluids with which it comes in contact. Certain experiments now in progress promise to give more information on this subject than that at present possessed, and when complete will receive due attention in these columns.

#### THE SURGICAL TREATMENT OF CEREBRAL TUMORS.

THE reactionary tendency noticeable of late in regard to the application of trephining and its modifications to a great variety of

cerebral affections makes any communication on the subject from Horsley, a high priest of modern brain surgery, particularly important. The subject he discusses in a late number of the *British Medical Journal* is "Surgical Intervention in Brain Tumors." Horsley does not even consider the general question as to whether operation is justified, provided brain tumor has been diagnosed and localized. This he assumes as a matter of course, and justly so, since, in spite of the long list of fatalities, it is generally conceded by all but the most conservative that operative interference is never more urgently called for than in certain cases of brain tumor. Starr, in his analysis of operations, tabulates eighty-one cases of tumors of the cerebral hemispheres treated surgically; fifty-four out of these eighty-one tumors were successfully located and removed from the brain; thirty-nine of the patients recovered and fifteen died. This, considering the fact that left to themselves death would have resulted in every instance, is sufficient justification.

Horsley states that, in the absence of localizing symptoms, operation is not to be considered. The localizing symptoms, of course, consist in attacks of Jacksonian epilepsy, or local contractions, or local auræ. As pressure becomes more marked, paralysis develops, either of motion or sensation, often somewhat sharply localized at first, but progressive in character. As corroborating symptoms, headache, vomiting, and optic neuritis are usually observed, though the presence of any or all of these last symptoms is by no means necessary for a positive diagnosis, the progressive character of the symptoms indicating the nature of the lesion more clearly than any other single feature of the case.

Given symptoms such as have been just detailed, the question as to how long medical treatment is justifiable is raised by Horsley, and is answered by the statement that six weeks is as long as can be expended in treatment by drugs unless a striking improvement in the symptoms has occurred. Starr names three months as the longest period for medical treatment, and it is allowable to postpone surgical intervention only when during this time there is no rapid increase in symptoms.

Of all the cerebral tumors, gumma and tubercle are alone amenable to medicinal treatment, at least in so far as a definite cure is concerned. It must be remembered, however, that all tumors may show a slight temporary improvement under the influence of iodide of potassium; hence the betterment of symptoms shortly following the inauguration

of specific treatment should not lead to a favorable prognosis being given too early, and particularly should not induce the practitioner to postpone surgical intervention until it is too late. Horsley personally does not believe that even truly gummatous tumors are permanently cured by drugs, though he is quite ready to concede the possibility of cure of tubercular lesions following the administration of arsenic, cod-liver oil, and other appropriate medicines.

Surgical intervention has for its object, primarily, of course, the removal and cure of the tumor. When the growth is strictly encapsulated, and when it is cortical and of moderate size, removal is readily accomplished. These conditions are almost never filled in the case of glyoma, the surgeon rarely being consulted until the growth is too widely disseminated for removal. The benign tumors, gummas and tubercular nodulations, if properly localized, may be removed with every prospect of success. Sarcomas, if taken in their early stages, while still encapsulated, offer a chance of non-recurrence.

But even though the tumor cannot be removed, and hence definite cure cannot be accomplished, operation holds out prospects of alleviation of suffering which more than justifies it. Thus trephining often serves to immediately and permanently relieve the agonizing headache and to put a stop to optic neuritis. Of course, when this process has advanced so far that atrophy has set in, the operation of trephining cannot restore sight, but if there is relief of intracranial pressure before the neuritis has reached its atrophic stage, there is often prompt subsidence of this process and consequently preservation of a satisfactory amount of vision. The vomiting is also, as a rule, immediately relieved by opening the skull, while in some cases the epileptiform attacks cease, or when paralysis has already set in there is partial or complete restoration of function. Indeed, in a few instances, malignant tumors have undergone a process of absorption after exploratory trephining.

Horsley narrates one case of cerebral tumor which could not be removed on account of its size. The tumor affected the ascending frontal gyrus of the left hemisphere. The patient lived for more than two years, with disappearance of the attacks and improvement of the hemiplegia. Post-mortem examination showed that the tumor, which at the time of operation was malignant and rapidly growing, had undergone complete destruction, in consequence of exposure at the time of operation.

As to the technique of the operation, Horsley objects to the use of the hammer and chisel for the purpose of raising a large flap consisting of the bone and soft parts adhering to it. For the removal of the bone he uses a special pattern of mechanical saw and powerful bone-forceps. In his earlier operations a large percentage died from shock. This he avoids by doing the operation in two stages. The first stage consists in exposing the skull and removing the bone. The wound is then closed and the patient allowed to recover. In a subsequent operation this skin flap is raised, the dura is opened, and the tumor attacked directly. The cavity left by the removal of the tumor he believes should be packed, since he lost a case from hemorrhage, the blood finding its way into the lateral ventricle and thence to the fourth ventricle.

Macewen for several years has performed his cerebral and cerebellar operations in two stages; this not only to lessen shock, but to allow the closure by inflammatory adhesions of the subdural space. He cites a number of cases showing the almost miraculous improvement which may follow palliative operations. In considering the subject of reimplantation of portions of skull removed during operation, he holds that, when large areas of the brain are exposed, it is well to preserve the contour of the cranium by replacing the whole slab of bone. Since, were this replaced exactly as removed, necrosis would probably take place, and since it is often difficult to drain when this large piece is put in position, Macewen drills a series of holes one-quarter of an inch in diameter, so that a mere lattice-work of bone is left. This allows of free drainage, and prompt organization takes place. Even if necrosis should occur, this is limited, and the dead portion is readily absorbed.

Cerebral localization has reached a point which apparently enables the surgeon to locate growths, especially in the motor areas, with almost absolute certainty, yet it is instructive to note that Starr's table of eighty-one cerebral tumors shows that the operation was unsuccessful in seventeen because the growth was not found by the surgeon at the point at which it was supposed to lie. Starr states that in some of these cases "the local symptoms were clearly insufficient to indicate the position of the tumor, and the cautious neurologist would not have advised an attempt to find it. In other cases the local symptoms were well marked and the diagnosis seemed clear, yet the tumor really lay at such a depth as to be inaccessible, or was so infiltrated in the brain as to make its removal impossible."

## Reports on Therapeutic Progress.

### TREATMENT OF CHRONIC ULCER OF THE STOMACH.

The great difficulty of properly treating stomach ulcers in private practice, owing to the careful dieting necessary, has led to a new mode of treatment. During the past four years DR. STEPP (*Therapeutische Monatshefte*, November, 1893) has used chloroform-water with bismuth subnitrate. The latter he does not consider necessary. He gave only the following formula:

Chloroform, 1 part;  
Aqua, 150 parts;  
Bismuth subnitrate, 3 parts.  
Sig.—1 to 2 spoonfuls hourly.

Dr. Stepp remarks that chloroform taken internally as aqua chloroformi is never an anodyne and has not the slightest pain-alleviating property. He gives the history of seven cases chosen from a very large number. As soon as the diagnosis is confirmed, the chloroform treatment can be begun. The refreshing taste of the chloroform-water combats most actively the nausea and thirst after the bleeding, and any tendency to further bleeding is stopped by the styptic properties of the chloroform. In new as well as long-standing ulcers there is soon a marked improvement; the color of the face improves vastly.

All the patients said that each time, after taking any, they felt a burning in a certain part of the stomach, doubtless the place of the ulcer, which disappeared after eight to ten days.

He never found any harmful influence upon the rest of the body.

### GALLANOL IN ECZEMA AND PSORIASIS.

In a brief article, P. CAZENEUVE and ET. ROLLET (*Lyon Médical*) call attention to the therapeutic value of gallanol in skin-disorders, particularly in eczema and psoriasis. In certain forms of subacute and chronic eczema gallanol proved to be a first-class therapeutic agent. Cases cured by it show no tendency to relapse, but the use of the drug must be conjoined with a suitable internal treatment and regulation of the diet. Under the influence of the medicament, itching and oozing disappear soon, and desiccation is rapidly established. For these cases gallanol may be employed in the form of powder, or in that of ointment

with traumaticine, in the strength of .5, 1, 2, and 3 grammes in 30 grammes. In psoriasis, especially in the mild form of the disease, the action of the new remedy is decided. The agent can be applied with advantage to the scalp, face, and neck, since its action is more rapid than that of alkaline substances. In these cases gallanol may also be employed in the form of ointment with lard or traumaticine, in the strength of 1, 2, and 3 grammes in 30 grammes. The parts must be thoroughly cleansed before the application of the medicament. The authors have similarly obtained good results from the application of a brush of this solution:

Alcohol at 93° F., 50 grammes;  
Gallanol, 10 grammes;  
Liquid ammonia, 1 gramme.

In these proportions the ammonia exercises no caustic action. In old, rebellious cases of psoriasis, gallanol seems to be less active than chrysophanic acid, pyrogallallic acid, and especially the iodo-chloride of mercury; but it has the advantage over these remedies in not being poisonous. Patients can handle the new medicament almost with impunity.

### SULPHATE OF MAGNESIUM IN THE SUMMER DIARRHŒA OF CHILDREN.

PATTERSON, in an article in the *Pittsburg Medical Review*, calls attention to the use of magnesium sulphate in summer diarrhœa, in an interesting communication. He believes the indications for treatment are to remove the cause, if known, and prophylaxis. To meet the first, sulphate of magnesium seems to him to be, theoretically at least, the ideal remedy. As to its practical utility, this report will speak conclusively. To meet the second indication, sterilize the food.

The administration of the sulphate of magnesium calls forth a profuse secretion from the intestinal glands. The remedy is a powerful alkali. It stimulates peristalsis, either directly or indirectly, through the quantity of secretion poured out or by producing a free flow of bile,—one of the natural stimulants to peristalsis.

Thus we have a remedy which, first, corrects the irritating properties of the contents of the stomach and intestines by rendering them alkaline; second, stimulates the glands to a more profuse secretion, thereby unloading a congested mucous membrane and possibly washing out the products of fermentation; third,

finally flushing the entire bowel, thereby removing the fermenting mass.

In the twenty-five selected cases treated by the author during the month of August, 1892, at the Pittsburg Free Dispensary, the symptoms were those usually found in the disease under discussion,—namely, vomiting, diarrhoea, ranging from the “chopped spinach” stools, mixed with mucus and streaked with blood, to the rice-water discharges, coated tongue, restlessness and general prostration, etc.

The ages ranged from one to six years. The dose and mode of administration of the remedy were as follows: The mother was directed to give a child a year old an even teaspoonful of sulphate of magnesium, sufficiently moistened to swallow, as soon as she arrived at home, the process to be repeated in the morning and the child to be brought back at 3 P.M. on that day.

This procedure was repeated daily at the same hours till the discharges became yellow. For the older children the dose ranged from a heaping teaspoonful to a heaping tablespoonful.

As a result of the exhibition of these doses, the mothers reported the children relieved of pain and restlessness with the induction of quiet sleep. No difficulty was experienced in the administration of the remedy because of its objectionable taste. The after-treatment consisted of general tonics and prophylactic precautions.

#### REPORT OF THE DURATION OF THE DISEASE IN THE SELECTED CASES.

	Days.
1.....	19
1.....	5
2.....	4
17.....	3
4.....	2

In the case lasting nineteen days the child suffered several relapses, owing to the mother's carelessness, and was finally sent to the hospital. The other twenty-four cases all did well and thrived under properly-regulated diet and tonics. The latter were selected according to the necessities of each case. Those most frequently used were syrup of iodide of iron, cod-liver oil, compound syrup of the hypophosphites, strychnine, quinine, pyrophosphate of iron, etc.

This list includes all of the cases that were selected for trial by this remedy, and the practically uniform beneficial results obtained in the treatment of this so often intractable disease warrant their record.

#### THE THERAPEUTIC USES OF ASAPROL.

DUJARDIN-BEAUMETZ and STACKLER (*Bull. Génér. de Thérapeutique*) have published an elaborate therapeutic study of this medicament. *Asaprol* is the sulphuric ether of betanaphthol, in the form of a calcium salt. The drug is exceedingly soluble. Its antiseptic equivalent is more or less that of the salicylate of sodium,—that is, in the proportion of 16 to 17. *Asaprol* is rapidly eliminated by the urine, in which it is detected by the addition of a few drops of the perchloride of iron, this process giving a bluish-black coloration.

The authors have administered the drug in doses of from 1 to 10 grammes (6 grammes being the medium amount employed), either in cachets of 1 gramme each, or, preferably, in solution in water, coffee, and other similar vehicles. They have used the remedy in a variety of disorders, as antithermic and analgesic: *a.* Acute and subacute polyarticular rheumatism, muscular rheumatism, muscular pains, etc. *b.* Influenza, various typhoid states, amygdalitis, pharyngitis, furunculosis. *c.* Certain cases of asthma were apparently relieved by the medicament. Similarly, as an analgesic, it was found serviceable in various neuralgic conditions, such as intercostal neuralgia, sciatica, and particularly dental neuralgia. The drug has rendered good service especially in the acute and subacute forms of polyarticular rheumatism, in muscular rheumatism, and in influenza. In doses of 6 grammes it has produced in the acute and subacute types of polyarticular rheumatism as good results as the salicylate of sodium.

A solution of *asaprol* in distilled water, intravenously injected into an animal, is more toxic than a similar solution of the salicylate of sodium; but by the stomach the former is incomparably better tolerated than the latter medicament. The salicylate of sodium often produces, even in small doses, first, vertigo, buzzing in the head, a peculiar cerebral disturbance, nausea, and vomiting; secondly, in patients suffering from albuminuria, the same amounts increase the quantity of albumin in the urine and cause nausea and vomiting. The salt, in one word, is apt to aggravate the condition of previously-diseased kidneys. The possible occurrence of these symptoms in patients suffering from renal affections constitutes, in the opinion of many physicians, the chief danger in the employment of salicylic acid. Therefore the administration of salicylate of sodium is condemned even in cases of slight albuminuria.

Asaprol is well borne: First, in doses of from 4 to 6 grammes, in the form of cachets or in solution, by patients who cannot tolerate the sodium salicylate, quinine, or antipyrin; secondly, in amounts of from 3 to 5 grammes, by dyspeptics who not only cannot tolerate any one of these medicaments, but who are unable to retain food; thirdly, asaprol never produces vertigo, buzzing in the head, cephalalgia, nor any cutaneous eruptions; fourthly, in patients who, in the course of an acute disease, suffer from a slight albuminuria, the drug, in doses of from 4 to 8 grammes, does not increase the condition, nor does it prevent its disappearance, the albuminuria passing off before the suspension of the treatment; fifthly, patients suffering from chronic nephritis, and in whom all medicine, all food, even milk, exercises a noxious effect, tolerate well the drug under study, in doses of from 3 to 4 grammes. In these cases asaprol does not increase the amount of albumin in the urine, neither does the medicament cause nausea, vomiting, or any nervous trouble. The authors, therefore, believe that neither the dyspeptic state nor renal disease, particularly those cases that rebel to the treatment by the salicylates, constitute a contraindication to the employment of asaprol in the doses mentioned.

#### THE TREATMENT OF TUBERCULOSIS WITH INJECTIONS OF SERUM OF IMMUNIZED DOGS.

In the Congress for the Study of Tuberculosis, held at Paris from the 27th of July to the 2d of August, 1893, BABES, of Bucharest (*Bull. Génér. de Thérapeutique*), treated of the above subject. Before Koch's time, Cornil, Leloir, and the author, in 1883, tried vaccination with attenuated tubercular matter of lupus against the most virulent forms of tuberculosis, but without positive results. During Koch's investigations, Grancher employed cultures of tubercle bacilli attenuated by age, and obtained remarkable results in the inoculation of a rabbit against tuberculosis. The personal experience of Babes, the results of which were announced to the Académie de Médecine in 1890,—that is, before the publication of Koch regarding the nature of his remedy,—demonstrated that tuberculosis of birds and its products render guinea-pigs less susceptible to tubercular infection. Later, Courmont, Héricourt, and Richet have confirmed and extended these results by showing that the dog, which appears to be refractory to bird tuberculosis, may be rendered refractory

to human tuberculosis by injections of cultures from bird tubercles. The researches of the author on the dog, in this respect, have not been conclusive, yet he has observed two dogs that have continued to resist the inoculation of even large quantities of cultures of human origin, after they had been subjected to the action of considerable amounts of virulent cultures from bird tuberculosis. He has employed a process of immunization, which consists in using tuberculin at the beginning, then continuing the vaccination with old and fresh cultures of both bird and human tuberculosis, and augmenting the power of resistance in the animals experimented upon by periodically inoculating them with increasing doses of cultures and their products of virulent tuberculosis. This method, however, has not been attended with success, and is often accompanied by serious complications. Of seventy-two inoculated animals, only seven were found to be immunized in the course of about one year. These unsatisfactory results are believed by the author to be due, on the one hand, to microbial associations, and, on the other hand, to the parenchymatous nephritis produced. The method, therefore, should not be resorted to in human therapeutics.

Since the serum of the dog is absolutely harmless to man, Babes has recently employed the serum of immunized dogs in the treatment of human tuberculosis. The dose administered has varied from 5 to 10 grammes of antitubercular serum to which has been added a one-per-cent. solution of phenic acid. The cases treated have been few, and as yet no positive conclusions can be drawn, but the author affirms that the tubercular patients subjected to the treatment have been benefited. He therefore recommends the employment of preventive inoculations of serum of strongly-immunized dogs in children of tubercular parents, and who are almost sure to become affected with the hereditary disease.

#### ICHTHYOL IN THE ABORTIVE TREATMENT OF ERYSIPELAS.

HALLOPEAU (*Les Nouveaux Remèdes*) details an interesting case of erysipelas, in which the most satisfactory results were obtained from the local application of ichthyol. The remedy speedily stopped the progress of the disease. The results confirm, according to the author, the great efficacy and the complete innocuousness of the treatment of erysipelas by ichthyol, and lead to the safe statement that in this drug we have a remedy that is capable of aborting

erysipelas in the course of twenty-four hours, and at any period of its evolution. Hallopeau employed a mixture in which collodion is substituted by a solution of gutta-percha and chloroform, this latter known under the name of *traumaticine*. The combination, which has a syrupy consistence, is as follows:

R Gutta-percha,  
Chloroform, of each, 25 grammes;  
Ichthyol, 50 grammes.

This is applied, not upon the diseased parts, but around these, that a barrier may be formed, so to speak, against the progress of the malady.

#### THE USE OF SALICYLATE OF SODIUM IN PLEURITIS.

DR. HERZ (*Wiener Medizinische Wochenschrift*, No. 41) replies to remarks made on an article in which he reported three cases of pleuritis successfully treated with salicylate of sodium, which article appeared in 1889.

Since that time he has treated over thirty cases in most varied stages of the disease, always with good results. There was no formation of exudation where the case came under treatment early.

#### THE ACTION OF SALICYLIC ACID ON THE WOMB.

PROFESSOR C. BINZ (*Berliner Klinische Wochenschrift*, No. 41) reviews the literature of the action of salicylic acid upon the womb, after having a case in which the use of seventy-five grains of it within a few days produced an abortion at three months.

Binz thinks the salicylic acid is not alone to be blamed in the cases reported, since its action was only bad in thirty-three per cent. of the cases, and these not the ones where the largest doses were given.

He concludes that at present we may gather:

1. That salicylate of sodium is worth trying for painful, late, and insufficient menstruation.
2. If for rheumatism, etc., it seems to be indicated, it must be given with caution if a tendency to miscarriage or premature birth exists, or where one is not sure of the contrary. The same holds also of the tendency of the non-pregnant womb to bleeding.

Binz hopes such a useful remedy will not be abandoned, but that it will continue to be cautiously used during pregnancy, and that further experiments will give us more exact proof of its action.

#### ATROPINE FOR CHRONIC MORPHINE- POISONING.

PROFESSOR W. KOCH (*Therapeutische Monatshefte*, November, 1893) reports a severe case of chronic morphine-poisoning which he treated successfully with atropine. The patient was a lady of thirty-eight years of age, who had used morphine injections for fifteen years. When she came under Dr. Koch's care she had, after leaving an institution, obtained large quantities of morphine on the journey home. Her eyes were glued shut with severe conjunctivitis. There was a considerable collection of mucus in the bronchi, which was not expectorated. The rattling sounds were constantly audible all over the room. The skin was moist, covered with viscid sweat; there was severe stomachache, vomiting, severe diarrhoea, constant unrest. The patient lay on her back in bed; there were twitching movements of the legs. She was without the least interest in her relatives, simply demanding more morphine and strong hypnotics; 45 to 60 grains of chloral were given internally or in an enema. When using 7 grains of morphine in twenty-four hours, marked signs of deprivation of morphine appeared. The strength diminished more rapidly, all bad symptoms increased, specially the collection of mucus in the bronchi.

This condition induced Professor Koch to try small quantities of atropine. Of compressed tablets, containing  $\frac{1}{8}$  grain morphine and  $\frac{1}{16}$  grain atropine, he gave two during the first four days. These produced a marked improvement in the general condition; the bronchial catarrh and diarrhoea were specially improved. In the first four days  $10\frac{1}{2}$  grains morphine was the minimum; after eight days only  $4\frac{1}{2}$  grains were necessary. From the fifth to the eighth day only one morphine-atropine tablet was injected, and at the end of ten days  $\frac{3}{4}$  grain sufficed. The patient had grown heavier, could walk, and the lameness had, by the use of electricity, nearly gone. But when the morphine was still further lessened, the insupportable hunger for it produced a very depressed state, so he was obliged to give another tablet. He was finally, after two months, able to get her into fairly good condition and using only  $\frac{3}{4}$  grain of morphine daily. When sent home she soon relapsed again and returned, so that he used the morphine-atropine tablets five times, each time with the same result.

He concludes that,—

1. Atropine removed in a surprisingly short time the severe exudation of the air-passages, the bowels, and the skin.

2. The atropine moderated very much, as it seemed, the symptoms due to the abstinence from morphine and hastened the possibility of gradually withholding it.

**THE ABSORPTION OF SALICYLIC ACID  
THROUGH THE SKIN AND THE  
TREATMENT OF ACUTE  
RHEUMATISM OF  
THE JOINTS.**

PROFESSOR DR. BOURGET (*Therapeutische Monatshefte*, November, 1893) gives a review of the efforts to prove how much of any substance is absorbed through the skin. He gives brief histories, with temperature charts, of nineteen cases of acute rheumatism which were treated only externally. The diseased joint was anointed with ten-per-cent. salicylic salve and bound with flannel. The result proves that no internal dose is necessary; but having thus proved this, Bourget says he will use in future small doses of a salicylate preparation, preferably salacetol, in daily doses of from 15 to 30 grains. The pain is quieted with great rapidity by the external treatment. The swelling also diminishes rapidly and the fever falls gradually. He thinks the internal dose will prevent a slight relapse, which frequently occurred on the fourth, sixth, or even the eighth day. Complications were very rare; in the nineteen cases only twice did a slight pericarditis occur. In one instance it was accompanied by a slight effusion, which was quickly absorbed; there was no effusion in the other.

In conclusion, he finds that,—

1. Salicylic acid is quickly and intensely absorbed through the skin. The skin of young persons is much more capable of absorption than that of older ones, and the skin of blondes is more readily penetrated than that of individuals with black hair or dark skin.

2. The rapidity and strength of this skin absorption depend upon the vehicle with which the salicylic acid is used. Only when fatty substances are used can the skin absorb it readily; when vaseline or glycerin is used, the absorption either does not take place or is very slight.

3. The treatment of acute joint rheumatism with a salve prepared from salicylic acid and turpentine is very much to be commended.

4. This salve is less efficient in other forms of rheumatism, but may serve as an aid to massage in treating them.

5. In cases of gonorrhœal rheumatism it has no effect.

**THE ACTIONS OF APOCODEINE.**

From an elaborate experimental study of the physiological actions of apocodeine, L. GUINARD (*Lyon Médical*) draws the following interesting general conclusions:

1. Apocodeine, contrary to what is generally held, is not an emetic.\* When the drug produces nausea, it is probably due to impurities and to its containing small amounts of apomorphine.

2. When .002, .010, or .048 gramme of apocodeine hydrochloride per kilogramme of the body-weight are intravenously injected into a dog, there is immediately produced a great nervous excitement, followed by violent convulsions, in the midst of which there are perceived symptoms of cerebral depression. During this convulsant period there occur acceleration of the heart's action and of the respiration and an elevation of the bodily temperature. This action of the drug may also be observed secondarily, after subcutaneous injections of from .05 to .06 gramme per kilogramme of the body-weight.

3. When apocodeine is administered hypodermically, in the proportion of .025 to .035 gramme per kilogramme of the body-weight, it only produces a calming effect on the dog. It causes a slight, quiet sleep, without provoking emesis or primary excitement. This phenomenon resembles the physiological sleep; the animal assumes a normal attitude, and, on being approached, awakes without evincing unusual disturbances, and, on the whole, does not show the peculiar hyperexcitability characteristic of animals under the influence of morphine. The same effects are produced by intravenous injections of apocodeine, but in these instances the drug should be introduced in dilute solutions and very slowly.

4. The disappearance of the soporific effects takes place in a simple manner; the animal awakes, but does not show the symptoms of hebetude and general malaise following the action of morphine. Four or five hours afterwards no trace of the medication is observed. The action of the drug is generally fugacious.

---

\* After the publication of this study had begun, Fröhner, of Berlin, published a paper, in which he declares, like the author, that apocodeine is not an emetic, nor does it produce nausea. The same Fröhner, without having made any analysis, pointed out the expectorant and narcotic properties of the drug, produced upon the dog, in hypodermic doses of .25 gramme. He does not describe the character of the sleep produced by apocodeine, and only and simply compares it with the narcosis caused by morphine.—*Monatsh. f. Praktische*, No. 6, vol. iv., 1893.

Apocodeine is rapidly eliminated, especially by the kidneys.

5. Following the administration of a calming dose of apocodeine, there almost always occurs a short period of cardiac and respiratory acceleration, accompanied by a slight elevation of the arterial pressure. On the other hand, during the period of sleep produced by the drug, both the heart and the respiration are slowed, and the arterial pressure is maintained at a little below the normal height. The slowing of the heart is not accompanied by disturbances in its rhythm, there being no intermittences. The action of apocodeine upon the heart is of medullary origin, as shown by previous section of the vagi. The diminution of the blood-pressure appears to be due more to the slow action of the heart than to an active vaso-dilatation.

6. During the somniferous action of apocodeine there is a reduction of the temperature varying from  $1.8^{\circ}$  to  $2^{\circ}$  F. This phenomenon is probably due, 1, to the immobility of the animal and to muscular relaxation; 2, to the modifying influences exercised on the heart and the respiration, and on the interchange of gases.

7. Under the influence of apocodeine there is produced a diminution of the intrapulmonary and intraorganic interchange of gases, manifested, 1, in a decrease of carbon dioxide and an increase of oxygen in the expired air; 2, in an increase of both the oxygen and carbon dioxide in the blood. This phenomenon is analogous to the one observed by Arloing during the hypnotic action of chloral, and to that noticed by the author in his studies of morphine, showing that there appears to be a distinctive peculiarity between an hypnotic action and an anæsthetic action.

8. Apocodeine, in all doses, produces always a hypersecretion of saliva, of bile, of the pancreatic and intestinal juices, and of that of the majority of mucous glands. These hypersecretory effects are the result of a central action and not of a special influence exercised by the medicament upon the peripheral elements, particularly the glandular ones. The experiments performed on this part of the subject support conclusively the statement just made.

9. Intestinal peristalsis is considerably increased by apocodeine, such functional change being due to an exciting influence exercised by the drug upon the ganglionar sympathetic centres.

10. The changes produced by apocodeine originate in the primary actions exerted upon the nervous system. They first show them-

selves upon the brain, but they are afterwards extended to other parts of the organism. These actions are depressant when the dose ingested is moderate; depressant and afterwards convulsant when the dose has been large but slowly administered; and, finally, convulsant from the onset when the dose is so introduced as to be rapidly absorbed by the organism.

11. The depressant effects upon the medulla spinalis, as shown by the posture assumed by dogs under the influence of apocodeine, are secondary; they are slowly produced and very moderate in those animals that have been deprived of the brain or in which previous section of the medulla has been practised. This last remarkable fact only shows the dominant action of cerebral centres upon the lower ones and their susceptibility to the action of drugs. The primary depressant effect upon the brain is communicated to the medulla oblongata and to the cord, and determines a functional inertia of these inferior centres which, without the influence of the brain, resist for a long time the direct action of the drug in question.

12. As depressant effects upon the cord may be produced independently of a cerebral action, the convulsant effects of apocodeine and the accompanying disturbances are similarly the result of a direct action upon the cord.

13. The convulsant action of the drug is followed by sensory and motor paralysis of the whole nervous system, these phenomena being best observed in frogs.

14. The previous administration of apocodeine, as in the case of morphine, favors the consecutive action of an anæsthetic.

15. During the sleep produced by apocodeine, the pupil is but little changed; it is dilated during the convulsive period, especially when the dose is poisonous. This dilatation attains its maximum in dogs, and especially in cats.

16. Cats show the same resistance to the depressant cerebral action of apocodeine as they do to the somniferous action of morphine. To these animals the drug under consideration is always excitant, enormously increasing the secretions and producing death by tetanus.

17. Comparing the effects produced by apocodeine with those caused by codeine, there will be found well-marked analogies, especially in regard to the ability of both drugs in producing sleep and in exercising a convulsant action. But a close examination of the subject will also show that there exist between the two medicaments notable differences in their actions. Codeine is less powerful as a hypersecretory and calming agent, but a more active

convulsant and more dangerous, therefore, than apocodeine. This last substance, although less powerful than codeine, is, on the other hand, more constant in its effects.

On the whole, the author, judging from the results obtained in his elaborate research, does not hesitate to recommend the *substitution of apocodeine for codeine in all those cases in which the former medicament is indicated and employed.*

#### EXPERIMENTS AND CLINICAL OBSERVATIONS ON THE ACTION OF CHLOROFORM.

In the *Lancet* is given an interesting account of a study upon the effects of chloroform.

The results of fifty experiments performed on animals at the Veterinary College of Glasgow is believed to prove that when chloroform is inhaled there is an action exerted by the vapor on the respiratory tract, and that a reaction ensues when the inhalation is discontinued, while it is maintained that both experiment and clinical observation combine to show that this reaction is the cause of primary syncope when allowed to take place at certain stages of the inhalation. A most important question, therefore, is, How long does the vapor take to escape from the lungs when the inhalation is discontinued? Dr. Snow concluded from the odor of the breath and from an observation on a man who inhaled the smoke of a cigar, that the vapor was completely discharged from the lungs with three expirations, and Kirk's observations on patients and on a rabbit, cat, and dog confirm this and seem to show that the lungs must be emptied in from ten to twenty seconds. The time taken to charge the lungs may be passed over, as well as the probable effects which are produced by the action of the vapor, for the reaction which follows is the most important question to be considered, and constitutes in itself an irrefragable proof of the action that had taken place previously. It must here be mentioned that rabbits, cats, and small dogs were chloroformed in a large glass vessel with a close-fitting lid, of a capacity of four thousand five hundred cubic inches, and which had been previously charged with a given percentage of vapor. When observations were made on the heart, the action was previously determined by auscultation, a binaural stethoscope being used in all but a few early experiments. An experiment on a rabbit and another on a guinea-pig seemed to show that no reaction of any importance with respect to the heart's action occurred in these animals. No observations on the pupils were made in these cases, but it may

be claimed for those which were made on the pupils of the cat that they led to results of the most beautiful and decisive character. When a cat's pupil is dilated it is circular, as it contracts it becomes oval, and it finally, in the strongest contraction, appears as a mere line. The yellow iris so common in cats renders pupillary changes easy of observation. In one experiment a cat inhaled four per cent. of chloroform for two minutes. When taken out of the jar the pupil was widely dilated, and it contracted to a minimum in fifteen seconds; this lasted for forty-five seconds, when there was sudden and wide dilatation and the cat recovered. In two other experiments the contraction took place in ten seconds and the sudden dilatation occurred a minute afterwards. Similar results ensued in two cats that breathed four per cent. of chloroform for one minute. This contraction cannot depend on further absorption, for so long as the cat remains in the vapor the pupil remains dilated; and it is equally clear that it must be due to a sudden reaction, otherwise the pupil would gradually return to its normal condition. In deeper anaesthesia these results were considerably modified, but they may be meanwhile omitted.

It now remains to show that the vapor reaction leads to stoppage and great irregularities in the action of the heart in cats. A considerable number of experiments were performed to determine this, but it will only be necessary to instance a few. In four experiments four cats inhaled four per cent. of chloroform for one minute. In one instance the observation was a failure, owing to the resistance of the animal, and in another the cardiac rate, which had been 140 before the inhalation, was extremely rapid when the cat was taken out of the jar; but there was a sudden stoppage in half a minute, which lasted for about five seconds, and this was followed by extreme irregularity for a minute and a half, when the cat recovered. There were pauses between individual beats in this case, sometimes after every third beat, while the sounds were very weak during this irregular action, and the same may be said of other cases. In the other two experiments the results were similar, rapid but regular action of the heart, ending in sudden stoppage and irregularities in about half a minute. In two other experiments, in which two cats inhaled the same percentage for two minutes, there was not much difference in the results. In eight experiments the several cats breathed three and a half per cent. of chloroform for two minutes, and subsequent stoppage and irregularities occurred in five of these. In one the heart was

irregular when the animal was taken out of the jar, but stoppage did not occur till some time afterwards. In another the cardiac rate, which had been regular and quick when the animal was taken out of the jar, became extremely irregular with frequent stoppages in half a minute, and this condition lasted for no less than four minutes and was associated with convulsive movements of the muscles of the thorax, the irregularities of the heart being more marked when the latter occurred. This is important to notice, as the concurrence of these two phenomena, though rare in cats, is common in dogs, and probably also in the human subject. Two days after the eight preceding experiments were made, the five cats that had shown irregular action of the heart being caused to inhale the same percentage of chloroform (three and a half per cent.) for a longer time,—for four, five, six, seven, and eight minutes respectively,—more or less irregular cardiac action occurred during recovery in all, and in two it was marked and prolonged; but it was observed that the irregularities were longer in manifesting themselves. In one, for instance, the cardiac rate had been 180 before inhalation and very regular, but after inhalation of chloroform for five minutes it was found to be 140 and regular; it suddenly rose about the beginning of the second minute after the administration was suspended to over 200; at the end of the second minute irregularities began, with changes in the “lubdupp” difficult to describe, and continued for eight minutes; and it was ten minutes from the commencement before the cat recovered. In the next case, in which another cat remained in the same percentage for six minutes, slight irregularities occurred in two minutes after cessation of the inhalation, but the cardiac action became regular in three minutes after removal from the vapor, and the animal recovered completely in less than five minutes altogether. In the last of the five experiments, in which a cat inhaled three and a half per cent. of chloroform for eight minutes, the cardiac rate was distinct and fast (240) for four minutes after, but it then suddenly became slow and irregular, and this continued for two minutes, when the cat recovered and the heart was found to be quite regular (160).

These results showed that very deep anaesthesia in the cat did not always modify reactionary effects on the heart, but the fact that the stoppages were longer in occurring after deep anaesthesia proved that the latter were not due to absorption of the chloroform, and that they could only be accounted for by the vapor reaction. The cardiac rate was often 240

during the reaction and the irregularities were coincident with a very sudden slowing. The binaural stethoscope permitted auscultation with very little pressure on the chest-wall. In a few experiments (with a long stethoscope) the cardiac action and the state of the pupils were observed at the same time, and it was found that contraction of the pupils was coincident with rapid action of the heart, and that dilatation corresponded with slowing and irregularity. It will have been observed that when the irregular heart's action was of short duration, the cat recovered in less time than it had been exposed to the vapor of chloroform, but that if the irregularity lasted longer, it was quite otherwise,—facts which are of great importance. The irregular action commences when the last drop of chloroform has left the blood, but as long as it continues the animal is as passive as if under the influence of a profound dose of the agent.

Forty experiments having been thus far performed in the inquiry, there remained only ten to be done on dogs. A very pronounced struggling stage takes place in the latter, this being almost entirely absent in cats. When this was at its worst, auscultation was found to be impossible, and it was often aggravated after the administration of the chloroform had ceased; but the observations which were made when the struggling had somewhat subsided, or even after it had passed off, were sufficiently conclusive. These showed that the dog was liable to similar stoppages of the heart as the cat, and that they were almost invariably associated with spasms of the respiratory and other muscles. They further showed that deep anaesthesia modified or altogether prevented these effects on the heart, and this is a vital part of the inquiry. It was found, moreover, that immediately after the struggling stage, and when the animal was quiescent, the anaesthesia was, nevertheless, not deep enough to prevent irregular cardiac action. In an experiment which was made on a male terrier, about two stone in weight, the animal inhaled two drachms of chloroform from a warm, dry towel for one minute. For the first minute during recovery the action of the heart was very rapid, but owing to some struggling it could not be counted. The struggling then became so violent that the dog was released, and it rolled on the floor for two minutes, moving its legs with great rapidity. On becoming comparatively quiet, the heart's action was found to be feeble and very irregular, there being frequently pauses between every beat, while the beats were very weak. In another experiment on the same animal, which was made six days afterwards, the dog inhaled four per cent

chloroform in the jar till complete anæsthesia was induced. Previously to this the action of the heart had been slightly irregular, the rate being from 116 to 120. All movements ceased in two minutes, and the dog was removed from exposure to the chloroform after one minute more, when it was found to be quite motionless and relaxed. The action of the heart was found to be regular and slow (88) for half a minute, but it rose regularly during the next half-minute, and during the second minute it was 140, regular, full, and strong, when the dog recovered. In another experiment, a small dog, fourteen pounds in weight, breathed four per cent. of chloroform till twenty-five seconds after the struggling had ceased, being quite flaccid when removed from the jar. Nevertheless, the heart's action, which had been regular when the dog was removed, soon became extremely irregular, and then rose to 240, subsequently slowing to 140, with marked irregularities lasting for fully a minute. When, some days afterwards, the same animal was kept in the vapor for one minute after it had become flaccid, there was no irregular action of the heart during recovery. Four more experiments with other dogs gave similar results.

It is maintained that the stoppages and irregularities of the heart, as above described in experiments on cats and dogs, correspond with and explain the fall of blood-pressure to zero which has been observed by some experimenters after the administration of the chloroform has been discontinued, and also the syncope of sudden failure of the pulse which has been so often noted clinically in the human subject. According to this view, chloroform syncope is analogous to syncope from other causes. The sudden removal of pressure from a large blood-vessel—i.e., the cessation of a force previously acting—may cause syncope. When men have been subjected to a pressure of several atmospheres they cannot be brought back suddenly to the normal atmospheric pressure without incurring the danger of syncope, and this syncope may prove fatal. Further, it has been seen that chloroform syncope coincides with a sudden transition from a quick to a slow cardiac rate, and the same has been observed in some other forms of syncope. Some clinical observations that have been made at the Western Infirmary, Glasgow, with a binaural stethoscope, may be briefly noticed. In one case the heart's action rose from 100 to 152 in half a minute, and in another it rose from 84 to 132 during the first minute, and to 152 before the expiration of one minute and a half, and similar results were seen in other cases. In all in-

stances the cardiac rate returned to normal just as the patient was pronounced "over," and only one case occurred which tended to prove that the quickened cardiac rate, instead of gradually slowing, may suddenly drop to a slow action, just as we have seen it do in dogs and cats. In this case the cardiac rate rose in two minutes to 132, and so continued for the next minute, but during the fourth minute there was an instantaneous fall to 96, although the action continued to be tolerably regular. It is probable the chloroformist allowed a vapor reaction to occur by not renewing the dose of chloroform soon enough. What were the consequences? The patient began to talk loudly and to struggle violently, and within a minute his breathing gave cause for anxiety. If it be objected that the reaction did not give rise to syncope in this case, the answer is that it was less in degree than it might have been, and there can be no doubt that these milder instances occur frequently. The coincidence with experimental results to be remarked is the instantaneous transition from the quick to the slow cardiac action, and this has been found to be associated in other cases in the human subject with irregular action and actual syncope. Deep anæsthesia in dogs and the human subject prevents this untoward result, but space forbids the discussion of the question why this should be so. The chloroformization ought to go on to deep anæsthesia in spite of coughing, struggling, or apnoeal pauses of even a whole minute's duration. The use of the binaural stethoscope would be of great value in our infirmaries, and might be expected to throw light on disputed questions.

#### AMMONIUM CHLORIDE AS A REMEDY IN CYSTITIS.

DR. GEORGE CORRIE has published in the *Virginia Medical Monthly* his views concerning chloride of ammonium in catarrhal states.

Directing his attention somewhat particularly to the diseases of the pelvic organs, the writer has had the opportunity to make trial of numerous vaunted agents, old and new, for the relief of cystitis, and finding the simple chloride of ammonium so much superior to all others, calls the attention of the profession thereto.

Some of the conditions mentioned demand operative or other measures for radical cure, but the above-named drug will be found of material service in preparing cases for operation, in palliating cases unsuited for operation, and as an adjuvant where other treatment constitutes the main feature.

A No. 1 capsuleful of Squibb's pulverized purified ammonium chloride should be taken three or four times in the twenty-four hours, preferably when the stomach is somewhat empty, each dose to be followed immediately by a half goblet or a goblet of pure cold water.

The following are some of the conditions in which the drug has been given faithful trial, with most satisfactory results in *every instance* :

Cystitis dependent upon stone in the bladder, stricture, hypertrophy of the prostate, deposits of urates, etc., gonorrhœa (male and female).

Cystic irritation from uterine disease or menstrual disorders, malarial effects, masturbation, early pregnancy, simple urethritis (traumatic) in newly-married women.

Cystic and renal sequelæ of *la grippe*.

In the majority of cases it was surprising to note the rapidity with which the urine was cleared of bladder mucus, blood-corpuscles, pus-corpuscles, urates, phosphates, etc., the distressing symptoms disappearing therewith, and in no case did the salt occasion any gastric or other disturbance when taken as ordered.

No explanation of the *modus operandi* of the remedy is offered. Only practical experience is here given, with the sincere hope of aiding those whose opportunities have been limited in the treatment of the diseases of the genito-urinary organs.

Fill the capsules only as needed for administration, as the salt dissolves the gelatin in a short time.

**PRACTICAL OBSERVATIONS ON THE FORMULAS AND ACTION OF CERTAIN DIURETICS AND PURGATIVES IN THE TREATMENT OF SOME FORMS OF DROPSY, RESULTING FROM VARIOUS CAUSES, AS CARDIAC AND RENAL DISEASES.**

In the *Virginia Medical Monthly*, DR. JOSEPH JONES contributes a paper on this subject.

The successful treatment of dropsy must be based upon a knowledge of its various causes and effects and upon the action of the various remedies employed.

Derangements of the due relationship of secretion to absorption in the tissues and cavities of the body may depend upon,—

1. Derangements in the nutrition of the tissues, leading either to the increase of secretion or diminution of absorption.

2. Derangements or alterations of the blood, leading to derangements of the nutrition of the tissues, with an increase of secretion or diminution of absorption.

3. Derangements of the circulatory apparatus attended with venous obstruction and congestion, increased serous effusion from the distended blood-vessels, and diminished absorption.

4. Derangements of the functions of those organs which regulate the amount of the blood, as well as its constitution, by regulating the amount of the watery element by the elimination of excrementitious materials.

A. Dropsy arising from the prolonged action of the malarial poison, characterized by destruction and diminution of the colored blood-corpuscles, splenic enlargements, and hepatic derangements.

Chronic hepatitis, parenchymatous hepatitis, portal obstruction, anæmia, and general anasarca are frequent results of the prolonged action of the malarial poison in the valley of the Mississippi.

The remedies best adapted to relieve the distressing and dangerous conditions induced by the prolonged action of the malarial poison may thus be enumerated :

(a) Sulphate of quinine, bromide of quinine, valerianate and hydrochlorate of quinine.

(b) Arsenic (arsenous acid, Fowler's solution).

(c) Iron (the various preparations of iron,—sesquichloride, citrate of iron and quinine, tribasic phosphate of iron, etc.).

(d) Mercurials in occasional doses to relieve hepatic congestions and derangements, as blue mass, calomel, bicarbonate of sodium and calomel.

(e) Saline purgatives, as bitartrate of potassium, Rochelle salt, sulphate of sodium, and sulphate of magnesium.

(f) Diuretics, as juniper-berry tea, nitric ether, jaborandi, pilocarpine, digitalis, etc.

The results are doubtful in those cases in which the liver has been structurally altered by the prolonged action of the malarial poison.

B. Dropsy resulting from valvular disease of the heart, mitral and tricuspid obstructions.

Valvular disease of the heart is attended with more or less hepatic obstruction, and benefit is often experienced by the judicious use of mercurials. Purgatives and diuretics are essential.

The agents used in the treatment of cardiac dropsy may be considered in connection with the following class :

C. Dropsy resulting from various structural alterations of the kidneys, included generally under the head of Bright's disease, acute and chronic nephritis, parenchymatous and inter-

stifial nephritis, gouty and cirrhotic kidney, etc.

In this class of dropsy (C), as with that indicated by B, all portions of the cellular tissue, as well as the abdominal and pleural cavities, may be enormously distended with serous effusions, and the skill of the physician is often taxed to the uttermost to relieve the great embarrassment of the circulation and respiration.

The lesion of the kidneys attended with albuminuria may result from the cardiac lesion, and the latter may also result primarily from the former. In many cases great and immediate benefit may be derived from various purgatives and diuretics.

The following formula may be used in many cases of dropsy arising from cardiac and renal lesions:

R Bitartrate of potassium,  $\mathfrak{z}$ xvi.

Divide into 16 packages. Add 1 pint of boiling water to 1 package (1 ounce) of bitartrate of potassium and 1 ounce of juniper-berries. Place the juniper-berries (1 ounce) and the bitartrate of potassium (cream of tartar) in a small porcelain pitcher or vessel. Cover the mouth of the vessel with a piece of mosquito-netting or strainer, so as to prevent the juniper-berries from pouring out.

Sig.—Stir well the bitartrate of potassium in juniper-berry tea, and drink a wineglassful every three or four hours, so as to consume the entire pint in twenty four hours.

This mixture will induce both purgation and diuresis, and will in many cases rapidly induce the reduction of the most extensive and obstinate dropsies. The tincture and extract or infusion of digitalis will greatly promote the diuretic action of the juniper-berry tea and cream of tartar.

The writer employs 6 to 10 drops of the tincture of digitalis every three, four, six, or eight hours, with marked benefit in many cases of cardiac and renal dropsies.

It is probable that digitalis is used in too large doses and in a reckless manner, and often with fatal results, by many practitioners.

In some cases the practitioner may resort to various diuretics in addition to digitalis, as jaborandi, pilocarpine, uva ursi, buchu, acetate of potassium, nitrate of potassium, sweet spirits of nitre (nitric ether), and other agents.

Several combinations are beneficial, such as the following diuretic wine for œdema, general anasarca, and dropsy in cardiac and renal diseases.

R Fluid extract of jalap,  $\mathfrak{f}$ zii;  
Fluid extract of squills,  $\mathfrak{f}$ ziii;  
Fluid extract of jaborandi,  $\mathfrak{f}$ zi;  
Fluid extract of digitalis,  $\mathfrak{m}$ xxx;  
Nitrate of potassium (pulv.)  $\mathfrak{z}$ iv;  
Angelica wine, Oii. M.

Sig.—One tablespoonful every three hours.

This diuretic and purgative wine has given the most satisfactory results in the speedy and wonderful relief of the most extended dropsical effusions resulting from valvular disease of the heart.

A diuretic mixture similar to that of Fothergill is also useful in dropsy resulting from cardiac disease, as,—

R Spirits of chloroform,  $\mathfrak{f}$ ziv;  
Acetate of potassium,  $\mathfrak{z}$ iv;  
Tincture of digitalis,  $\mathfrak{f}$ zii;  
Infusion of buchu to make in all  $\mathfrak{f}$ 3x. M.

Sig.—One to two tablespoonfuls every two to four hours.

We have thus presented a few practical observations and suggestions, with the hope that they may prove of practical value.

In the treatment of the dropsical effects of hepatic, portal, cardiac, and renal lesions and obstructions with purgatives and diuretics, the physician should endeavor to sustain the strength of his patients. No fixed rule can be laid down as to the amounts of the various diuretics and purgatives to be used in any given case; each case should be carefully examined and studied, and the effects of each remedy used carefully watched. The results of the treatment will depend largely upon the nature and extent of the organic lesions.

In cases of ascites dependent upon cirrhosis of the liver, much may be accomplished by purgatives and diuretics to prolong life and overcome the constant tendency to the accumulation of serous fluid in the abdominal cavity, and when these measures fail, we must remove the fluid by the trocar.

In many cases of cirrhosis and ascites, caused by excessive spirit (alcoholic) drinking, we have frequently removed by successive tapplings hundreds of pounds. Sooner or later these cases of ascites perish from the exhaustion caused by the repeated tapplings. In one case of cirrhosis of the liver occurring in an Irish laborer, who had consumed enormous quantities of rum, gin, and whiskey, it was necessary to evacuate the serous fluid from the abdominal cavity almost every seven or twelve days; from one to two gallons of serous fluid were evacuated at each operation. The patient died at the end of the sixth operation. Throughout his illness his intellect was clear.

In ascites resulting from the cirrhotic condition of the liver, death speedily ensues, if the distended abdomen of the patient is not relieved by the trocar.

Under all circumstances, and even in necessarily fatal cases, the physician may accomplish valuable service by relieving suffering and prolonging human life.

## THE ACTIONS OF URETHANES.

In an elaborate research, PAUL BINET (*Revue Médicale de la Suisse Romande*) has studied the actions of ethylurethane, methylurethane, acetyl-ethylurethane, acetyl-methylurethane, and thio-urea. In regard to the first four bodies, the author has found that the introduction of the radical acetyl ( $C_2H_3O$ ) in the group  $NH$ , of the ethers of carbamic acid is followed by no remarkable alteration in the toxic phenomena produced. Again, this radical, being inactive, overpowers the molecule, so to speak, and diminishes its toxicity. For example, in the young white rat, weighing about one hundred grammes, the minimum fatal doses by subcutaneous injection are as follows: Methylurethane, from .40 to .45 gramme; acetyl-methylurethane, from .80 to .85 gramme; ethylurethane, from .20 to .25 gramme; acetyl-ethylurethane, from .50 to .55 gramme. The increasing toxicity, taking 1 as the unit, may be put down in this manner: Acetyl-methylurethane, 1; acetyl-ethylurethane,  $1\frac{1}{2}$ ; methylurethane, 2; acetyl-methylurethane, 4. These figures indicate the relative toxicity among these substances in the case of the rat. Otherwise considered, the acetyl derivatives are about one-half less poisonous than the corresponding urethanes. As to their molecular weight, these bodies may be grouped in an ascending order, as follows: Methylurethane, 75; ethylurethane, 89; acetyl-methylurethane, 117; acetyl-ethylurethane, 131. The toxicity does not, therefore, increase in relation to the molecular weight when looked upon in the arrangement just described, but it does increase in relation to the molecular weight when the urethanes and their acetyl derivatives are considered separately. Thus, for instance, ethylurethane possesses at the same time a greater toxicity and a greater molecular weight than methylurethane; similarly, the acetyl derivative of ethylurethane possesses a greater toxicity and a greater molecular weight than acetyl-methylurethane. On the other hand, the acetyl derivative of ethylurethane, although it has a greater molecular weight, is less toxic than ethylurethane; the same may be said in regard to acetyl-methylurethane and methylurethane.

The author has also endeavored to determine whether the toxicity of the molecule itself is in any way modified by the introduction of the acetyl radical. Dividing the toxic doses by the respective molecular weight, the following figures were obtained, indicating the relative proportion of molecules contained in each dose: Acetyl-methylurethane, 7; methylurethane,  $5\frac{1}{2}$ ; acetyl-ethylurethane, 4; ethyl-

urethane,  $2\frac{1}{2}$ . Now, taking 1 as the unit of toxicity for acetyl-methylurethane, the following are the relative molecular toxicities for these different bodies: Acetyl-methylurethane, 1; methylurethane,  $1\frac{1}{2}$ ; acetyl-ethylurethane, 2; ethylurethane, 3. In other words, the molecule of acetyl-ethylurethane is twice as toxic as that of acetyl-methylurethane; that of ethylurethane three times as toxic, and so on.

The author proposes to term *molecular toxicity* the relative toxicity of bodies with regard to the numerical proportion in the number of molecules contained in the toxic doses. It is obtained by dividing the toxic dose by the corresponding molecular weight of the body. The molecular toxicity of the urethanes is expressed thus: The molecule of ethylurethane is twice as toxic as that of methylurethane; similarly, the molecule of acetyl-ethylurethane is nearly twice as toxic as that of acetyl-methylurethane. The relative toxic powers of the urethane are not, therefore, notably altered by the introduction of the acetyl radical. The introduction of this radical in the group  $NH$ , of the urethanes diminishes the toxicity of the molecule; the loss is about a third. Thus, the relative molecular toxicity of acetyl-ethylurethane being represented by 2, that of ethylurethane is represented by 3, a difference of one-third. Similarly, the molecular toxicity of acetyl-methylurethane being 1, that of methylurethane is  $1\frac{1}{2}$ , a difference of one-third.

The preceding results were obtained in albino rats; similar results were observed in other animals, with slight differences. The rabbit and the rat are more susceptible to the action of urethanes than the dog. Both the rabbit and the rat exhibit more or less the same susceptibility to the influence of urethanes. Thus, for the rabbit the urethanes show a toxicity similar to that seen in the rat, the toxic doses being practically the same. This is shown by the following figures, obtained for every one hundred grammes of the animal's weight: Acetyl-methylurethane, .50, toxicity, 1; acetyl-ethylurethane, .40, toxicity,  $1\frac{1}{3}$ ; methylurethane, .25, toxicity, 2; ethylurethane, .12, toxicity, 4. Therapeutically considered, the acetyl derivatives of the urethanes, being less active, appear to be more advantageous than the corresponding urethanes.

From the results of this investigation the author draws the following general conclusions:

1. The first bodies of the series of urethanes are more active proportionately to the increase

in molecular weight of the combined alcoholic radical.

2. The acetyl radical introduced in the group  $\text{NH}_2$  of the urethanes does not notably modify the physiological properties of the molecule, but diminishes the toxicity of this by an equivalent weight. For the rat and the rabbit the relative toxicities, in an ascending order, are as follows: Acetyl-methylurethane, 1; acetyl-ethylurethane,  $1\frac{1}{2}$ ; methylurethane, 2; ethylurethane, 4.

3. The term *molecular toxicity* is applied to the relative toxicity determined by the quotients of the toxic doses divided by the molecular weights. Such toxicity is diminished by the introduction of the radical acetyl in the group  $\text{NH}_2$  of the urethanes.

4. The physiological action of the urethanes, like that of their acetyl derivatives, consists essentially in a narcosis of the central nervous system, during which the great functions are not interfered with. Under toxic doses the animal succumbs from collapse, with progressive relaxation and weakness of the heart.

#### THE TREATMENT OF SMALL-POX BY MERCURIAL BATHS AND INUNCTIONS.

R. RICHARDIÈRE (*L'Union Médicale*) publishes an interesting report of the cases of small-pox occurring at the Hospital d'Auber-villiers from February 15 to the end of December, 1892. There were in all one hundred and ninety-seven cases,—one hundred and five of true variola and ninety-two of varioloid. Out of the one hundred and ninety-seven patients, fifteen died, giving a mortality of 7.5 per hundred. Of eighty patients subjected to the antiseptic treatment, only ten died, a result which may be considered good, since in most of these cases the disease assumed the gravest character. The cause of death in these ten cases was adynamia in five of the confluent variety of the disease, diffusive suppuration of the neck and broncho-pneumonia in one each, diffusive gangrene of the lungs in an alcoholic, hemorrhages in an advanced tubercular patient, and uræmia in one case of infectious nephritis. Among the complications which occurred in the non-fatal cases are mentioned: Unilateral epididymitis (non-suppurative), 1; more or less intense pulmonary congestion, 4; broncho-pneumonia, 2; dry pericarditis, 1; phlegmasia alba dolens during convalescence, 2; bed-sores. 1. The majority of patients made a good recovery, without presenting during the period of convalescence such complications as furunculosis, ecthyma, or

multiple superficial abscesses, so frequent before the antiseptic treatment of small-pox was instituted. Erysipelas was *never* observed. As intimated, suppurations during convalescence were exceedingly rare, occurring only twelve times in the one hundred and ninety-seven cases of small-pox observed, and of these twelve, seven cases belonged to varioloid patients or those in whom the mercurial bath was not applied. On the whole, the treatment has given satisfactory results. It consists simply in the application of mercurial baths and inunctions. The patients are bathed twice a day at regular intervals. The bath must have an ordinary temperature,—that is, from  $33^\circ$  to  $35^\circ$  C.,—and must be of a duration of fifteen minutes. Each bath must contain ten grammes of corrosive sublimate dissolved in alcohol. These baths are given twice a day up to the time when the bodily temperature has declined definitely, or just up to the end of the suppurative stage of the malady. During the period of desiccation one bath every twenty-four hours is sufficient. After the crusts begin to fall off, the mercurial is substituted by a simple bath containing some boric acid in solution. The mercurial baths act upon the pustules of the trunk and extremities, but not upon those of the face. The latter are best treated, according to the author, by the following method: The head and face of the patient are covered by muslin bandages that have been previously dipped in a solution of corrosive sublimate of the strength of fifty centigrammes to the litre. A sort of helmet or casque is formed with this bandaging, leaving intact, of course, the natural openings, such as the eyes, nose, and mouth. The bandage is allowed to remain during the course of the disease, and after its first application is simply wetted several times a day with the mercurial solution, without removing it. This method is of great value and is well borne by the patients. The author affirms that cases of small-pox treated in this manner do not exhibit any form of dermatitis or vesicular eruptions following often the local application of mercury. In the cases reported a milk diet was strictly observed; ordinary diet was only allowed two or three days after the bodily temperature had assumed a normal character. No remedial agent was administered internally, and only in adynamic cases was stimulation resorted to.

#### THE ANTIPYRETIC ACTION OF GUAIACOL WHEN LOCALLY APPLIED.

This subject, first, we believe, brought to the notice of the profession by an article of Bard,

and of which we published an abstract in a recent number of the *GAZETTE*, receives support in the results obtained in three tubercular cases reported by E. ROBILLIARD (*Gazette Médicale de Paris*).

The author concludes as follows :

1. The local application of guaiacol diminishes the temperature more rapidly and constantly than the sulphate of quinine. This reduction is considerable, consisting of several degrees.

2. The part of the cutaneous surface selected, like the extent of it, is of no importance. The drug has been applied over the chest, on the arms, and over the thighs, without observing any difference in the results.

3. The dose of guaiacol employed may vary, but it seems that the application of .50 gramme is sufficient to produce excellent effect. I believe that the question of purity of the drug is of the greatest importance. I have made applications with an impure guaiacol, resulting in the production of an intense burning and redness over the skin.

4. Patients favor the medicament under consideration. They soon feel the good effects. All those that I have observed have exhibited a considerable increase in the perspiration and a marked taste of guaiacol in the mouth. The secretion of urine is apt to be abundant. I have searched for the presence of guaiacol in the urine, but the results have been negative. However, it is sufficiently demonstrated that the medicament is absorbed from the skin. The taste of the guaiacol appearing in the mouth of patients cannot be attributed to the introduction of the drug by the breathed air, since care has been exercised in covering the applications with impermeable court-plaster and a good bandaging. That the antipyretic effects of the drug are not due to the imagination is evident from the fact that I have made applications with water colored with carmine, and no reduction of the temperature has been noticed in these instances.

---

*THE SEDATIVE ACTION OF DUBOISINE,  
WHEN GIVEN IN CONTINUED  
DOSES, IN THE TREAT-  
MENT OF THE  
INSANE.*

Under the above title, E. MARANDON MONTYEL (*Archiv. de Neurologie*) publishes interesting details of thirty-five cases of mental derangement treated by duboisine.

From the results obtained the author formulates the following conclusions :

1. Duboisine is a marvellous sedative, capable of allaying always and in all cases lypemania and maniacal excitement, whether of a vesanic or of a paralytic nature, and of producing an absolute calmness in excitable or the most violent cases. The action of the drug is always effective and manifests itself in two phases,—the one an incomplete attenuation of the excitement; the other a complete one, characterized by a total disappearance of the pathological condition, and which lasts for a more or less lengthy period of time.

2. The sedation caused by duboisine is not always of the same intensity; generally, it does not come on until the second day, sometimes not until the third day after the administration of the drug.

3. Once produced, the sedation of the drug is maintained steadily, provided a habit is not made manifest; exceptionally, good and bad days alternate.

4. The action, even when complete, often persists one or two days after the ingestion of the drug has been stopped, and sometimes longer.

5. In the intermittent or remittent forms duboisine is capable of reducing the duration of the crises and of prolonging the intervals between them.

6. The sedative action of duboisine, particularly during the first days of its administration, is generally in inverse ratio to the time which has elapsed after the ingestion of the remedy, and hence the advantage of giving the daily amount of the medicament in two doses.

7. The action of duboisine is more frequently complete in chronic than in acute mania; and, on the contrary, more so in acute than in chronic lypemania.

8. In general paralysis the complete action of duboisine is less frequent than in chronic mania or acute lypemania, but more so than in acute mania or chronic lypemania; and, similarly, more frequent than in mania or lypemania in general; so that, in a total of cases of general paralysis, the sedative influence of the drug was more marked in these than in those cases of a vesanic nature.

9. The organism of the class of patients here considered becomes often and quickly accustomed to the influence of duboisine, and this habit—which, as a rule, is established abruptly—once produced, rebels, ordinarily, to increased doses of the drug; this is true particularly in regard to the production of complete sedation.

10. The duboisine habit occurs more frequently and more rapidly in cases of general paralysis than in those of a vesanic nature, or

of acute and chronic mania and chronic lypemania; it is the same in general paralysis as in acute lypemania, and of more frequent occurrence in lypemania than in mania; finally, it does not come on in chronic vesanic cases.

11. The incomplete action of duboisine is less frequent in general paralysis than in vesania, but more frequent than in chronic mania and acute lypemania; it is less frequent in mania than in lypemania, in chronic than in acute mania, in acute than in chronic lypemania.

12. In general terms, it may be said that duboisine is more active in cases of general paralysis than in vesanic cases, in mania than in lypemania, in chronic than in acute mania, and, *vice versa*, in acute than in chronic lypemania.

13. Owing to the influence which duboisine exercises on the stomach, it is better to administer the drug, in order to obtain a sedative effect, during the day and as long after each of the two principal meals as possible.

14. Unfortunately, duboisine acts in a deleterious manner on the process of nutrition, especially when given for a long time. This action is to be feared, and, notwithstanding the marvellous sedative properties of the drug, is a drawback to its employment, particularly when the use of the medicament is to be prolonged.

#### THE VALUE OF ANTISEPSIS IN THE TREATMENT OF HEPATIC COLIC AND BILIARY LITHIASIS.

An interesting article is published by E. CASSAET and L. CORNET (*Archiv. Cliniques de Bordeaux*), containing the details of two cases of the nature referred to above, in which happy results were obtained by antiseptic treatment. In Case I. all the troublesome symptoms of biliary retention yielded to the action of salicylate of sodium combined with large doses of olive oil, by the elimination of a very large calculus. The dose of the salt was 5 grammes during a period of twelve days, followed by the ingestion of 300 grammes of olive oil in six doses, at intervals of half an hour, for three days. In Case II. the same symptoms disappeared under the use of large quantities of corrosive sublimate. The first dose of 30 grammes of Van Sweiten's liquid, in two equal amounts, morning and evening, was given. A second dose of 50 grammes was then administered, divided in three equal parts, at intervals of several hours, the patient taking in the mean time large quantities of milk. A third dose of 100 grammes, in four equal amounts, during the

day, was ingested, associated with the administration of 300 grammes of milk. The most important result in both cases was the rapid disappearance of the infectious symptoms attending the migration of the calculi. The authors entertain the hope that the use of the salicylate of sodium in long-continued doses, and that of corrosive sublimate in massive amounts, if necessary, may in every case abate the serious phenomena of angiocholitis and post-calicular cholecystitis, not only by preventing the formation of new calculi, but also by provoking the expulsion of those already in existence.

#### THE INJECTIONS OF NERVE-SUBSTANCE IN THE TREATMENT OF THE INSANE.

A. CULLERRE (*Gazette Méd. de Paris*) publishes the details of fourteen new observations with the use of nerve-substance in the treatment of insane patients. The author summarizes his experience as follows: The injections of nerve-substance, practised aseptically, are inoffensive. They have the property of increasing nervous power, especially that presiding over nutritive functions. They are, therefore, useful in the treatment of mental derangement. The first effect of this mode of treatment of the insane is the amelioration of the appetite. Certain patients, particularly those subjects of a more or less prolonged abstinence, show an almost bulimic disposition, their appetite becoming insatiable. The bodily weight increases in a short time and often to a considerable extent. Muscular power is renewed; the organic functions become regular; menstruation reappears; uterine hemorrhages disappear, as do the neuralgias accompanying them. The cachectic state, when not the result of an organic affection, such as nephritis, cancer, etc., is not a contraindication to the employment of the injections, and, on the contrary, these are of service. Tubercular patients are sometimes benefited by them. This medication appears to be efficacious in the course of certain acute maladies, when the usual modes of treatment have proved of no avail, and when an unfavorable prognosis authorizes the use of bold therapeutic means. But, notwithstanding all these merits, the injections of nerve-substance have failed to strengthen the hopes we had entertained after the happy results obtained in the treatment of neurasthenia. *They are impotent against the psychopathic element itself.* The mental state, in curable cases, is only slightly influenced by the injections of gray substance, and sometimes only ameliorated for the time being, during the

few hours immediately following such injections; but this effect (with the exception, perhaps, of a single case, not fully demonstrated at that) does not persist, and no lasting amelioration is obtained.

#### *TREATMENT OF PERFORATED GASTRIC ULCER.*

Naturally the most disastrous accident which can occur to the patient suffering from gastric ulcer is perforation, and the results are more to be dreaded than acute hemorrhage. In the *Birmingham Medical Review*, MR. BARLING contributes a paper on this subject.

The record of his three cases is so instructive that they will bear careful inspection. They emphasize many points. First of all, that a patient may die of perforation without anything in the previous history to suggest the presence of an ulcer of the stomach,—that is, the ulcer is latent. In two cases the history points to a period of quiescence in the symptoms for some time before perforation took place. Then it will be noticed that in the first two cases the perforating ulcer was on the anterior wall of the stomach,—a point of some importance in the treatment, because here the ulcer will often be accessible for suturing. The general impression appears to be that most of the perforations are to be found on the posterior wall, or, at all events, not on the anterior; but it is to be doubted if this would be borne out by statistics. Again, these three cases indicate the class of patients most subject to the accident of perforation; all of them were young women and all taken from the same social class.

One of the most important points they illustrate, however, is that cases of perforation may vary greatly in acuteness and intensity. Nothing could well be more acute or intense than the peritonitis found in Case I., in which the abdomen was opened six hours after the perforation had taken place. In Case II., on the contrary, the escaped stomach-contents were evidently circumscribed for a time between the liver and the stomach, and the peritonitis was of a milder degree and more limited in area, so much so that perforation was hardly suspected by those who first saw the patient. In the third case the escape of stomach contents was so limited that the peritonitis was quite mild, and subsided almost entirely until the twentieth day, when the acute symptoms developed.

The fact should be emphasized that though some patients die almost outright from the

shock of perforation, and a majority in from twenty-four to thirty-six hours from an intense peritonitis, yet in a few cases the symptoms are subacute, or even subside for a time, to be followed by an acute extension which will prove rapidly fatal.

What is the fate of a patient with an ulcer of the stomach which has perforated, if surgical measures are not resorted to? Available statistics do not show, but from a careful scrutiny of numerous cases the mortality is not exaggerated in giving ninety-five per cent. or greater. In medical literature every now and then one comes across a case of recovery recorded, and though not all of these are conclusive, yet there are sufficient cases submitted to autopsy to demonstrate the possibility of recovery by the ordinary treatment for peritonitis and keeping the stomach empty. It is necessary to realize the fearful mortality of perforation, because failure will often follow on surgical interference, and it may excite regret that the disease was not treated by medical means only. The right way to view the matter is to regard each patient who recovers after operation as one saved from almost certain death.

Before speaking of treatment it is advisable to see what it is we may be called on to treat. From a scrutiny of numerous cases it is clear that we may have at least three conditions present,—1, a very acute and widely-spread peritonitis; 2, a circumscribed peritonitis, which may or may not eventually become diffused; 3, a circumscribed peritonitis which is mild in its commencement, which eventually suppurates and gives rise either to an acute and fatal peritonitis or perforates into an adjacent cavity, as the thorax or colon. The diagnosis of perforation of the stomach is, as a rule, not difficult. The patient is commonly a young woman, oftenest of the servant class, or an elderly male. There is very generally a history of indigestion, which has given rise to the suspicion of gastric ulcer even if a positive diagnosis has not been made, but the symptoms may have been in abeyance for a time before perforation takes place. The symptoms of perforation are generally unmistakable. The patient complains of intense or, at all events, of very severe pain in the abdomen, this generally after a full meal or after making some exertion. The pain is wide-spread, and collapse sometimes of a profound character follows. The pain may later be localized to the upper part of the abdomen or to the left hypochondrium. Vomiting sets in, the pulse is quick and small, the belly becomes rigid and tender. Then we have the usual phenomena of a very

acute peritonitis if the patient survive the immediate shock,—abdominal distention, rapid breathing and pulse, pinched facial look, lividity of the lips and extremities. An occasional sign which has been made much of is the diminution—in some cases the disappearance—of liver dulness, which may be due either to the presence of free gas in the peritoneal cavity, from the stomach, or to a distended coil of bowel getting in front of the liver.

A diagnosis, then, can usually be made; but occasionally the progress of the case appears to throw doubt upon it. This was so in the third case; and, curiously enough, a somewhat similar case occurred in an adjacent house, in which perforation was diagnosed. A girl with symptoms of gastric ulcer was, after a period of quiescence, seized with extreme pain in the abdomen, collapse, tenderness on pressure, and vomiting. With morphine and complete rest for the stomach, the symptoms so completely subsided that the diagnosis was much doubted; but the following day an attack of retching brought on a further leakage from the stomach, and the patient speedily died, the conditions mentioned being substantiated by autopsy.

A diagnosis of perforation having been made, operation should follow as speedily upon it as circumstances will allow. It is not possible to tell in the early hours whether the escape of stomach contents is much or little, whether the perforation is on the anterior or posterior wall of the stomach, or whether there is any probability of the extravasated food, etc., becoming localized. Under these circumstances, and recognizing the terrible mortality of perforation, it seems to be clear that *early operation* is urgently called for always when perforation has been diagnosed.

*Operation.*—With the limited experience at present available, it is undesirable that one should speak too dogmatically as to the exact lines to be followed, but the following are the main outlines. The abdomen should be opened in the middle line above the umbilicus, but not too near the costal margin. Positive evidence may at once be found of perforation in the presence of free gas or food. The area between the stomach and liver should be examined with care, so that any localized collection here should, if possible, be prevented from soiling the more distant parts of the cavity. Any extravasated matter having been removed, the perforation should be sought for on the anterior wall, especially towards the lesser curvature, where it will most commonly be found to exist. A perforation being found here, if accessible, should be sutured, the sutures being

applied with the stomach outside the peritoneal cavity, if this can be managed; but it will not always be possible. It will be wise to first pass a piece of drainage-tube into the hole in the stomach and run off any fluid the organ contains. In my second case, although no food had been administered for some time by the mouth, there were several ounces of thin, almost watery, fluid in the stomach, just like the material so constantly vomited in peritonitis, and which kept leaking from the perforation until it was completely removed by the tube. The most convenient form of suture to use is probably Lembert's; but if the hole to be closed cannot be brought outside the abdomen, the operator will find that he has a difficult task before him. It has been recommended that the edge of the ulcer should be pared before suturing. This was not necessary in the only one the author has sutured, for the edges of the ulcer were so tough as to hold the sutures well. If it were found that the edge was too friable, excision of it might be advisable; but even then the case would perhaps be met better by an extensive infolding of the margin, which could be done easily and without risk of kinking in the stomach. The objection to excising the margin is that it takes time to effect, and one of the most important factors militating against recovery in cases of this kind is prolonged exposure on the operating-table. If the ulcer cannot be sutured, it may possibly be stitched to the lower angle of the abdominal incision. If the perforation be inaccessible for suturing and cannot be brought up to the incision, the only resource left to the surgeon is drainage with a tube leading directly to the point of leakage. Though this falls short of the more complete proceeding, yet drainage has been found so efficient a protection against the extravasation of other fluids—as, for instance, bile—that one cannot but feel hopeful of it in this condition. Whether suturing be possible or not, it is of the greatest importance that the abdominal cavity should be washed out and thoroughly flushed with hot water. When the flushing out has been done, the drain should be placed *in situ* close to the perforation, whether it has been sutured or not. Something more than this is necessary, however. A second tube should be inserted into the abdomen just above the pubes, otherwise the drainage of the peritoneal cavity will be very imperfect, and a considerable quantity of fluid will collect in the pelvis and greatly interfere with a successful issue. It is probable that this accumulation interfered with the well-doing of the second case.

In the more chronic cases, such as the third,

the treatment should be different. An incision directly on to any inflammatory mass would be the right procedure, and in the event of pus or other fluid being found, this should be evacuated with the greatest care, to prevent fouling of the general peritoneal cavity. For this reason sponging is to be preferred to flushing for cleansing purposes, as the irrigation may carry infective particles to more distant parts, whence they cannot escape again, but may set up fresh mischief. A drain to the bottom of the abscess cavity is then required, and all that can wisely be done has been done. To search for the perforation, with a view to closing it, would be useless and dangerous.

Finally, for success two things are necessary,—*early diagnosis* by those who first see the case, and *operation* following on this as early as possible. Here hours are of as much importance as days in other conditions; in fact, there is hardly any emergency more urgent in the whole of surgery.

#### DEATH FROM NITROUS-OXIDE GAS.

Death from inhalation of nitrous-oxide gas is so unusual that any case should be reported and studied with interest. In the *Medical News*, THORNBURY reports such an accident.

Following some preliminary remarks regarding the effects of nitrous oxide, the following brief report is made of an autopsy in this particular case. The autopsy was held upon a woman who died after the administration of four gallons of nitrous-oxide gas by a dentist for the extraction of four teeth. Soon after the induction of anæsthesia the patient began to show signs of embarrassed breathing. Medical consultants were summoned. The pulse became rapid and attempts at breathing spasmodic. Artificial respiration was resorted to; the lower extremities were elevated. Nitro-glycerin ( $\frac{1}{100}$  grain) was administered hypodermically, and ammonia applied to the nostrils. The patient seemed to rally for a short time, but unconsciousness continued, the pulse became more rapid and feeble, and the heart's action finally ceased.

The body was that of a middle-aged female, fairly developed and poorly nourished. Post-mortem rigidity was slight. Post-mortem staining was present over the pendent portions of the body. The median incision showed the subcutaneous fat to be small in amount. No pleuritic adhesions existed in the thorax. The right lung weighed sixteen ounces, and was universally congested and œdematous; there was exudation of a large quantity of frothy serum. The left

lung weighed thirteen and a half ounces, and was also congested and œdematous. The lining membrane of the bronchi upon both sides were intensely hyperæmic and the tubes partially filled with frothy exudate. The heart weighed ten ounces, and was of normal size and color. The ventricles were firmly contracted, and the walls of the left ventricle were slightly thickened. There was a dark clot in the chorda of the mitral valve. There were three minute athromatous areas in the posterior wall of the aorta just above the segments of the valve. Over the anterior surface of the œsophagus were two areas of hemorrhagic extravasation, irregular in outline and about the size of a half-dollar. The tracheal mucosa was heavily coated by a frothy, removable mucus.

The larynx was congested, and the lining membrane was also covered with frothy, slightly blood-tinged mucus. The congestion was especially marked in and just below the ventricles. The aryteno-epiglottidean folds were considerably corrugated, suggesting pre-existing œdema. The position of the viscera was normal. The spleen was dark, moderately firm, normal in size and in consistency. The kidneys showed a dark-bluish discoloration; the surface was smooth, the capsule non-adherent. The right was slightly smaller than the left, and contained a blood-clot beneath the mucosa of the pelvis and the true renal substance. This clot occupied an area one-half a square decimetre in extent. The ureters were normal and the bladder empty. No urine was obtained for analysis. The liver was normal in size; its weight three pounds. The stomach was normal in size and contained about six ounces of partially-digested food. The mucous membrane was coated with thick, semi-tenacious mucus; the membrane was slightly slate-colored in appearance. The intestines were normal. The uterus showed catarrhal endometritis, and there was a small quantity of mucus in its cavity. The left ovary showed a very recent corpus luteum and there was also a small cyst present. The right ovary and the tubes were normal. The brain was not examined, owing to inability to obtain the consent of the coroner.

This case illustrates the invariable presence of danger in the administration of anæsthetics, even of the supposed harmless "laughing gas."

#### TREATMENT OF DIABETIC COMA.

In the London *Lancet*, HARLEY contributes a valuable paper on diabetic coma, and concludes as follows:

The rational treatment founded on the re-

sults obtained from the above-mentioned experiments is to administer alkalies. If the symptoms are urgent and time is of moment, sodium carbonate might be administered subcutaneously or intravenously, as recommended by Stabelmann, the pulse being carefully watched in case of heart-failure. At the same time, since the author's experiments have shown so great a diminution in the oxygen absorbed, it is advisable to encourage oxidation. The inhalation of pure oxygen may help, as well as trying to improve oxidation by massage. Diuretics, together with large quantities of fluids, will be of value in increasing the rapidity of the elimination of the toxic products derived from the sugar. These are the means suggested to ward off attacks of diabetic coma, or even to diminish the severity of a coma already set in.

#### INTRACEREBRAL HEMORRHAGE.

ESKRIDGE contributes a paper on this subject to the *Medical News*. He thinks that most patients while in the apoplectic state from cerebral hemorrhage would do better without medicine than they do when medicine is simply administered with the hope of doing some good, but the administration of which is not governed by any logical or rational principle.

If we bear in mind that in hemorrhage into the cerebral substance, not traumatic in character, the immediate cause of the hemorrhage is the bursting of a miliary aneurism, we shall appreciate how futile must be our efforts to arrest such a hemorrhage by the administration of medicine. Immediately after the occurrence of the event the indications are to allow the effused blood to coagulate, to promote the flow of the venous blood from the head, to quiet the heart's action, to allay the restlessness of the patient, when such exists, and to prevent an undue amount of blood being carried to the head. We can render the best service in aiding the coagulation of the effused blood by keeping the patient absolutely quiet. The flow of the venous blood is promoted by slightly elevating the head and shoulders, and not allowing the head to be bent forward, and thus compressing the veins of the neck. The heart's action is best quieted by the careful administration of small and frequently-repeated doses of aconite, when there are no contraindications to the use of this drug. Restlessness, when considerable, is most effectually relieved by a hypodermic administration of  $\frac{1}{4}$  grain of morphine; when it is slight,

sodium bromide is effectual. Various means are at our command to lessen the flow of blood to the head; sometimes one or two, sometimes all, should be employed. Brisk purgation should almost always be resorted to. If the stomach is not irritable, one drop of croton oil in ten drops of sweet oil should be placed on the tongue every hour until the bowels are opened freely. When the stomach is irritable, ten grains of calomel should replace the croton oil. Whether calomel or croton oil is employed, an enema, consisting of one ounce of salts, a half-ounce of glycerin, and four ounces of water, should be thrown up the large bowel as soon as possible after the occurrence of the hemorrhage. Mustard-plasters applied to the back of the neck, the front of the chest, and on the calves of the legs aid in lessening the quantity of blood carried to the head. Blood-letting is sometimes indicated, but cases necessitating the withdrawal of blood by opening a vein are probably rare.

In regard to the administration of ergot in the cases of cerebral hemorrhage under discussion, it does no good whatever, and there is a possibility of its doing harm. The practice of applying cold to the head, especially ice, in cases of non-traumatic, intracerebral hemorrhage is reprehensible. It seems rational to suppose that it may increase the engorgement of the intracerebral vessels. When the face is turgid, the head warm, and the carotids throbbing, ice-cloths or iced poultices may reduce the heat of the head and promote the coagulation of the effused blood.

It will be seen that the only routine treatment recommended for intracerebral hemorrhage is brisk purgation immediately after the occurrence of the accident, to which may be added the application of mustard-plasters to various portions of the body. In the subsequent treatment, during the acute stage, indications must be met as they arise. In the chronic stage, electricity and strychnine must be used with judgment and great caution. The routine employment of these two agents to overcome the paralysis does much harm by causing irremovable contractures of the arm and leg of the affected side. In this stage strychnine should not be employed when contractures are present or when the deep reflexes are greatly exaggerated. We must remember that no hard-and-fast rules can be laid down in regard to the use of strychnine. The author has seen cases in the acute stage in which this drug, in combination with aromatic spirit of ammonia, has done good service. When electricity is applied,—and, as a rule, it should not

be before the end of the fourth or sixth week,—the extensor muscles only should be stimulated, and during the application the extremities should be held in their normal positions. Massage, systematic exercise, Swedish movements, and time do most to overcome the residual paralysis of intracerebral hemorrhage.

#### THE TREATMENT OF CHOREA.

For a number of years, ESKRIDGE, of Denver, has refused to assume charge of a case of chorea if the parents and friends will not consent to follow his instructions. In the very mildest cases, in which there is only an occasional grimace of the face or an infrequent twitch of the muscles of the hand or foot, he allows the patient to sit up part of the day and spend the remainder of the waking hours on a lounge. No violent or exciting exercise, such as romping, running, etc., is allowed. The patient is placed on a nutritious, digestible, but non-stimulating diet. The stomach and bowels are kept in as good a condition as possible. The patient, to begin with, receives as many grains of antipyrin at bedtime as he is years old, and the dose is increased one grain each night until all twitching stops. At the beginning of the treatment of these mild cases he commences with 1 drop of Fowler's solution after each meal, and increases the dose one drop each day until the point of tolerance is reached; then the arsenic is discontinued for two or three days, or until all unpleasant effects of its administration have passed away, when the drug is again resumed at the dose reached when it was stopped. The dose is again increased one drop each day until tolerance is reached, when it is discontinued, and resumed after two or three days as before. As soon as the twitching ceases, the antipyrin at bedtime is discontinued, and the patient is given syrup of the iodide of iron after each meal, in from 3- to 10-drop doses, depending upon the age of the patient. The arsenic and iron are continued for two or three weeks after all symptoms of the disease have disappeared and the patient has regained considerable flesh.

In all except the mildest cases, to which reference has just been made, absolute rest in bed, day and night, is insisted upon from the first. If he had to rely upon one method of treatment in the management of chorea, to the exclusion of all others, he should unhesitatingly choose absolute rest in bed. When the little patient is placed in bed to begin its treatment (we will suppose it to be a child of a few years,

or not more than fifteen years of age), he orders as many grains of antipyrin three times daily, after taking food, as the child is years old, and increases the dose one grain each day until all violent movements stop, when he begins with 1 drop of Fowler's solution after each meal, well diluted in water, and increases the dose one drop each day, in the manner described. About the second or third day after the arsenical treatment has been added, the antipyrin is given only once each twenty-four hours, and the time for its administration is usually about eight or nine o'clock in the evening, thus securing a comfortable night for the little patient. After all but the most occasional twitching has stopped, the antipyrin is discontinued, and syrup of the iodide of iron is given in connection with arsenic. It seems a little heroic to give a child of seven years of age from 10 to 15 grains of antipyrin three times daily, yet he has given a child of eight years 20 grains of antipyrin three times daily, without the slightest apparent depression or untoward effect. Certain precautions, however, are necessary. In the first place, if there is any rise of temperature, perspiration will be free and depression will result. Antipyrin should be avoided in cases in which there is much rise of temperature. In such chloral hydrate takes the place of antipyrin. He has never carried the dose of the former to nearly that of the latter. When there is cardiac weakness, antipyrin and chloral should be given with great care, if at all. When such a complication exists, phenacetin, with a little cannabis indica, seems to quiet the patient. Valvular disease of the heart alone does not seem to contraindicate the employment of antipyrin, but cardiac dilatation does.

While antipyrin is being given the patient must be kept at rest in bed. He has seen considerable depression follow a large dose of antipyrin when the little patient has been allowed to run around. During the administration of large doses of antipyrin or chloral the patient should be seen at least daily, and the urine should be repeatedly examined.

The questions in regard to arsenic in chorea—How large doses may be given? How long should the drug be continued? Should it be kept at the point of tolerance for weeks without intermission, and what unpleasant effects are likely to follow its administration in large doses?—are pertinent.

How large doses of Fowler's solution may be given? As a rule, children from seven to fifteen years of age will bear larger doses of arsenic than adults. So far he has never found

it necessary to give very large doses to children under six years. In a number of instances he has given 20 drops of Fowler's solution three times daily to children from ten to fifteen years old, for a week or more at a time. In the majority of instances the point of tolerance is first reached when the dose has been gradually increased to some 6 or 7 drops thrice daily. After stopping the arsenic for two or three days, or until all unpleasant effects have passed away, and resuming its administration at 6- or 7-drop doses, as the case may be, the next point of tolerance will be attained when the dose has reached 10 or 12 drops thrice daily. In most instances all twitching will have stopped at this time. If such be the case, the medicine is resumed after two or three days, at this dose, but now it should not be increased. It should be given at the dose tolerated when the twitching has stopped, for a week or ten days, then discontinued for two or three days, and resumed again at the full dose. The dose is now lessened one drop each day until 4-drop or 5-drop doses are reached, stopped again for two or three days, and again resumed at 5-drop doses. Arsenic, as a rule, should not be continuously given in full doses for more than eight to ten days at a time. By observing this precaution he has been fortunate enough to avoid the ill effects that some physicians have reported from the continuous use of full doses of arsenic.

How long should the administration of arsenic be continued after all twitching has stopped? As a rule, it should be continued for a month or more after all choreic symptoms have ceased, but not in full doses of toleration for more than a week or ten days, when it should be stopped for a few days; then the dose should be gradually reduced, as recommended.

The next question—Should the large tolerated doses be continued for weeks without intermission?—has already been answered in the negative.—*Medical News*.

#### REMOVAL OF HAIR, MOLES, ETC., BY ELECTROLYSIS.

In the *Medical News*, SORENSON contributes an interesting paper on electrolysis, and reaches the following conclusions:

1. Do not begin with too strong a current.
2. Apply the current for a sufficient length of time.
3. Always apply the negative pole to the part it is desired to destroy.
4. Do not have the circuit closed when you

insert the needle, until you have learned to know your patient *electrically*, if such use of the word be permissible.

5. Always test the strength of your current before beginning. To do this it is convenient to touch the two poles to the tongue, having the points about an inch apart.

#### LOCAL ANÆSTHESIA BY ETHYL CHLORIDE.

GIBSON contributes to the *New York Medical Journal* a paper on ethyl chloride.

Ethyl chloride is one of the newest local anæsthetics. Gibson's experience leads him to believe that it is destined to occupy a useful place among our local therapeutic agents.

There are several preparations made by various firms, and, so far as the author has observed, of equal merit. The preparation the writer uses is that made by Dr. Bengue, of Paris. Its properties are thus described by the maker: "Ethyl chloride is a colorless liquid, with a slight ethereal odor of an agreeable character. The density is .874 at 41° F.; it boils at 52° F.; its vapor density is 2.219. Ethyl chloride is very inflammable, burning with a green-edged flame and setting free hydrochloric acid."

The anæsthetic comes in glass bulbs of the capacity of a little over an ounce. The bulbs are provided with a capillary orifice, upon which a tightly-fitting cap is screwed, preventing evaporation. One bulb furnishes sufficient anæsthesia for six to eight minor procedures. In using this agent the cap is first unscrewed and the bulb held in the palm of the hand, when the liquid will be instantly volatilized by the heat of the body. The bulb should be held horizontally and six to eight inches from the part, playing the stream back and forth as evaporation is produced. At first a hyperæmia results, then pallor, and gradually the part assumes a parchment-like appearance. From one to two minutes is needed, and anæsthesia lasts as long again.

Gibson's experience with ethyl chloride comprises some twenty-five cases of minor surgery, chiefly cellulitis of the fingers, abscesses of the jaw, buboes, sinuses, boils, and carbuncles. Most of the cases were relieved by a single incision, and in such the anæsthesia was most satisfactory. Where more extensive procedures were demanded, where deeper structures were divided, for efficient curetting, etc., the agent was seldom efficient.

Its action in certain cases, however, was ideal. In felons, for instance, the single rapid

incision was generally effected absolutely without pain. Every one that is called upon to incise felons knows how excruciating the pain is. The patient winces at the slightest touch; the introduction of cocaine solutions subcutaneously is almost a cruelty, as intense pain results both from the needle pricks and from increase of the tension in the indurated tissues. Moreover, the cocaine often proves powerless to overcome the aggravated conditions. It is especially in such conditions that chloride of ethyl will prove invaluable.

No attempts to use ethyl chloride were made in procedures requiring more than a few seconds' time, nor where careful dissection was needed, as the agent so changes the character of the tissues. It can, however, be employed to great advantage in removing small sections of tumors for microscopical examination.

It will occasionally be found useful to combine the action of the new agent with that of cocaine.

The author had recently to operate for ingrowing toe-nail on a young child. When he made the first prick of the needle, in order to cocaineize the parts for Anger's operation, the little patient grew so obstreperous that he could do nothing with her. The proposed line of insertion of the needle was then sprayed with the chloride of ethyl, obtaining enough anæsthesia to allow the introduction of the needle without attracting the child's attention, and the battle was won in favor of the operation.

The ethyl chloride will be found of considerable value in dermatological practice, especially for thorough scarification and application of the actual cautery. Dr. Bengue's bulbs intended for dental surgery are provided with curved nozzles, allowing the spray to be deposited on the desired spot. Gibson has had no opportunity to verify the use of this agent in such work. The following are Dr. Bengue's directions:

"In extracting teeth the jet should be directed to the dental nerves, as near their origin as possible; in front of the ear for the upper teeth, behind the angle of the inferior maxilla for the lower ones. The spray should be applied for about a minute; but the anæsthesia thus produced is not so complete as when the jet is applied directly to the gums, and, as this last method is devoid of danger, its use is advised in all cases except those of the last molars, which are not easily reached by the spray."

Differing from the usual action of those agents which act by refrigeration, no bad after-effects, such as great pain or sloughing of the tissues, have been noted by the writer. Care

should be taken that the jet is not brought into contact with a light or incandescent surface, as the substance is highly inflammable. The eye should be protected from the spray. General symptoms of poisoning may be produced by inhalation, according to Crocker.

The writer's attention was first called to the value of ethyl chloride as an analgesic by its success in the hands of a French gentleman in the treatment of a severe intercostal neuralgia. He has found it very efficient in treating the pain of a supraorbital and occipital neuralgia. The jet was played over the painful point for a few seconds at a time, being repeated at short intervals on recurrence of the pain, without the slightest bad after-effect. Dr. Bengue suggests the use of chloride of ethyl in a very extensive class of cases, among which may be mentioned all the forms of neuralgic and rheumatic pains, various hyperæsthetic and reflex conditions, and the various forms of colic.

Chloride of methyl, so far as he has witnessed its action in the hands of others, is identical in results with chloride of ethyl. It is less convenient to use than the preparation with which Gibson has experimented, as it is contained in little bulbs whose capillary end must be broken off before use, thus necessitating the employing of the entire contents at one sitting. A rough estimate of the cost of the ethyl chloride, as used in the above cases, is ten cents for each surgical anæsthesia.

#### POISONING BY CRYSTALLIZED ACONITINE.

VEIL reports in *La France Médicale* the case of a druggist who by accident took a pill containing 12 milligrammes of crystallized aconitine. The poison was taken at half-past eleven in the morning, and on the appearance of the very first symptoms the attending physician administered 20 grains of powdered ipecac and  $\frac{1}{16}$  grain of emetine. The stomach was also washed out. After the vomiting had occurred the patient noticed a sensation of burning in the mouth, about the face, and in the extremities. Forty minutes after the poison had been taken the face was pale, the voice was almost lost, there was a feeling of impending death, and loss of consciousness. The pulse was very small, difficult to count, and the action excessively rapid. The respiration was feeble and irregular. The extremities were cold and the skin was covered with a clammy sweat. At this time rubbing, with the applications of hot-water bottles and the injection of 15 grains of caffeine and 45 minims of sulphuric ether, was

resorted to. The pulse was now 40 to 50 a minute. The vomiting continued. After this iced champagne was administered and stimulating applications with friction were applied to the extremities. On the return of the physician two hours later the condition of the patient was still most alarming: the pupils were dilated, the skin was cold, the pulse completely lost, the respirations almost gone. The pulse was now 30 per minute, and the pupils became excessively dilated; there was also muscular trembling; the vomiting did not cease. At this time 15 grains of caffeine and 30 minims of ether were again given, and produced an improvement in the symptoms. The use of the caffeine to the amount of 7 grains was frequently resorted to throughout the night. The severe symptoms of intoxication disappeared after nine hours. The vomiting ceased during the night, under the influence of chloroform-water and elixir of paregoric. For two or three days the prostration was exceedingly severe, and at the end of the week the patient had not entirely recovered. The case is of interest, in view of the fact that ultimate recovery took place, and also of the valuable results obtained by the injection of massive doses of caffeine.

#### THE HYPODERMIC INJECTION OF THE SALTS OF QUININE.

In *L'Union Médicale* there is an interesting article upon the hypodermic injection of quinine, in which the following solubilities of the various salts are given:

1 part of neutral hydrochlorate is soluble in .66 of water; neutral sulphovinate, .70; neutral lactate, 2.00; basic sulphovinate, 3.30; neutral hydrobromate, 6.33; neutral sulphate, 9.00; basic lactate, 10.29; basic hydrochlorate, 21.40; basic hydrobromate, 45.02; basic sulphate, 581.

The neutral hydrochlorate is by far the most soluble of the salts of quinine for hypodermic use, and is, in addition, rich in alkaloid. The sulphovinate is also very soluble, but is not so advantageous. It has been found that the addition of antipyrin aids in the solubility of the quinine. As is well known, the hypodermic injection of quinine forms an important part of the treatment of cases of severe malarial poisoning.

#### THE HYPODERMIC INJECTION OF SALINES IN CHOLERA.

In *L'Union Médicale* a summary is given of the results obtained by this method. A solution is made, consisting of 5 parts of powdered

chloride of sodium, 10 of sulphate of sodium, and 100 of water. The temperature is 100° F. The quantity of the injection varies from 1 to 3 pints, and they may be given from three to four times a day. In the hospital at Hamburg, Jolasse has collected the following statistics from 1017 cases: Cases treated by subcutaneous injections, 104; deaths 92, cures 12. Cases treated by intravenous injections, 167; deaths 130, recoveries 37. Cases treated by both subcutaneous and intravenous injections, 48; deaths 44, recoveries 4. Cases treated by enteroclysis, 42; deaths 12, recoveries 30. Cases treated by internal treatment, 606; deaths 248, recoveries 358. In addition, there were 50 cases of cholera in which the treatment is not stated.

#### ARTIFICIAL SERUM FOR HYPODERMIC INJECTION AFTER SEVERE SURGICAL HEMORRHAGE.

According to *L'Union Médicale*, CHERON recommends the following mixture for injections under these circumstances:

℞ Sulphate of sodium, 3ii;  
Phosphate of sodium, 3i;  
Chloride of sodium, gr. xxx;  
Pure carbolic acid, ℥xv;  
Sterilized distilled water, 3xxvi.

The inside of the thighs, the abdominal wall, or loose tissues of the back are the proper points for these injections to be made.

#### AN ADDITIONAL NOTE ON THE USE OF STROPHANTHUS IN THE TREATMENT OF EXOPHTHALMIC GOITRE.

At the last meeting of the American Medical Association, DR. E. D. FERGUSON read a paper with the above title. He has not kept a detailed record of the cases coming under his observation, but has had about fifteen or twenty additional cases in which strophanthus has been used. In all of these an improvement has resulted, though the degree of amelioration of the symptoms has varied. In one, a young woman twenty-two years of age, who had exophthalmos in what might be termed a hideous degree, and was incapacitated for even moderate exercise by the tachycardia, the pulse-rate being, even at rest, from 160 to 180, Ferguson was unable to reduce her pulse-rate below 110 or 120; but though in appearance she is not notably improved by the treatment, she is quite gratified with the results, for she is able to attend to household duties and travel for pleasure, even enduring without inconvenience several days

of shopping in an occasional visit to New York City.

So far as he has been able to follow the cases related in his previous paper, the improvement has continued. There was no instance of a relapse, though some have been obliged to continue the use of the drug the greater portion of the time. The first case related in the previous paper—that of a woman now over sixty years of age, and who was an extreme sufferer from the disease—has been able to keep herself in a condition for active exercise by the nearly continuous use of strophanthus.

The fact that the tachycardia is often the earliest manifestation of the disease has enabled the author in two instances to suspect the approaching development of the exophthalmos and the goitre, and so bring the patient under the influence of the drug before notable deformity had occurred in relation to the eyes and the neck, though there was sufficient change to justify the diagnosis before the tachycardia was relieved.

The writer does not urge strophanthus as a specific in Basedow's disease, for while his own experience has uniformly given favorable results, it is manifest that this complexity of symptoms may be associated with irremediable changes in the nerve-centres, or there may be conditions more favorably influenced by other drugs or measures. Many cases benefited by strophanthus may need additional therapeutic agents, and in several he has felt the necessity for the administration of iron, arsenic, and strychnine. It seems that belladonna would prove of value in some cases, and next to strophanthus he regards it as our most valuable agent. He has not observed favorable results from electricity, but the fact that some of the cases are mild and tend to a favorable termination should be taken into consideration in forming our conclusions. He is satisfied that this favorable course in some cases has been the result of the natural tendencies of the disease, rather than any effect of therapeutic measures. In his early use of strophanthus he endeavored to protect his conclusions from error in that direction by limiting its use only to undoubted cases of the disease, but it so happened that the early trials were made in severe cases.

If the individual case is favorably influenced it will then be wise to inform the patient of the probable necessity for a prolonged use of the agent, for though a few months often seem sufficient in some cases, others may require its use for an indefinite number of years.

The question of dosage is one of considerable importance, for it varies greatly in indi-

vidual cases. When strophanthus was first introduced by Frazier its dose was given at from 4 to 7 drops of the tincture, but it was soon manifest that either the individual specimens of the drug differed greatly in potency or personal susceptibility was an important factor. It is true that from 5 to 10 drops will occasionally give notable results, but in his experience Ferguson has shown that much larger doses are often required. His present plan is to have the patient secure a sufficient quantity of the tincture to obviate the necessity for frequent changes of the preparation, and then to begin with 8 to 10 drops at each of the three daily meals, using always the same dropper. After a week, if no benefit results, this dose is increased by one or two drops, and in this way continued and increased until its beneficial results are obtained or until there is evidence of injurious effects, though so far he has not been obliged to cease from its use on account of toxic symptoms. Injurious or unpleasant effects will furnish indications relative to its continuance or the dosage.

In this way he has increased the dosage to 50 drops three times daily—an amount found by actual measurements to be about thirty-five minims—before relief was experienced, and this large dosage has been continued for several months, not only without unpleasant effects, but with great relief.

It seems the part of wisdom to have the patient purchase the drug in considerable quantity at each time, thus obviating the necessity for frequent changes in preparations; and when taking large doses it may be well to take somewhat less than the maximum dose when a new specimen is procured, for it is a clinical fact that the activity of the preparations is not uniform.

#### TOXIC EFFECT OF GALLIC ACID.

BELL (*New Zealand Medical Journal*, No. 3, vol. vi., 1893) reports the following case: T., aged thirty-two, male, had been suffering from internal hemorrhoids for two or three years. Latterly there had been venous hemorrhage with each movement of the bowels, etc. He had tried various remedies, such as cold water, etc., and had touched the piles with tinct. ferri perchlor. and liq. ferri perchlor. to check the bleeding. He had lost about a dessertspoonful of blood a day for two months or more.

Operation was advised, but he wished to give other remedies a trial first, and used hazeline, injected into rectum and also taken

internally by the mouth, for a time with no benefit; also chlorate of potassium. He then got some unguentum gallæ cum opio, and one morning applied it freely to the bleeding hemorrhoid just after a motion. The piles were not painful, and all discomfort ceased when the pile was replaced. There was no bleeding, nor did the pile come down except when the bowels were moved. After using the gall ointment the first time he had an attack of what appeared to be hay asthma; not severe. This was attributed to his having inhaled some irritating dust.

Three or four days afterwards he had a similar asthmatic attack, followed by an eruption of urticaria for three or four hours.

The hemorrhage from the piles still continuing freely at each motion, Dr. Bell asked him to use a 3-grain tannin suppository a short time before and after each movement of the bowels.

In the afternoon, feeling quite well, he inserted a suppository. In about four minutes the symptoms of the asthma began to appear. First there was pain and a tight feeling under the sternum and trouble in breathing; the breathing became quicker and labored, accompanied with wheezing and an occasional cough, until, in about half an hour from the time the suppository was introduced, all he could do was to lie on the bed gasping and straining for breath, face flushed, hot and perspiring, râles and rhonchi all over the chest, and pain on coughing. With each cough a little pellet of mucus was expelled. This condition lasted for another half-hour, and then the pain and rapidity of breathing began to subside, but then the attack of urticaria commenced. Starting about the head and neck, it extended all over the body, and became especially marked about the feet. The irritation and itching were intense. Some of the wheals were from two to three inches in diameter. At the end of about four hours the cough had stopped, the breathing had returned to normal, but the irritation of the skin continued in a less degree till next morning.

The patient has never had any asthma or anything approaching it before or since, nor have any of his relatives ever had anything of the kind; nor has he ever had urticaria or any skin eruption whatever.

There can be no doubt but that both these symptoms were caused by the absorption or irritation of the tannic or gallic acid applied to the hemorrhoid. None of the other drugs used, such as steel drops, hazeline, chlorate of potassium, etc., caused any symptoms like the

above, nor did the symptoms appear except when the tannic or gallic acid was used, so it can only be concluded that in some peculiar way the gallic acid has had a toxic effect. Both the drugs have been used frequently, by the chemist who made up the ointment and suppositories, for other patients without causing any such symptoms.

Later the patient agreed to an operation, but first of all went South for a change. Three or four days after leaving home and getting to a cooler and more bracing climate, the bleeding stopped, he felt much better, and ate better. In a fortnight the anæmia was gone, and although the piles still remained, yet they were so much improved that he decided not to undergo the operation at present.

---

#### THE USE OF COCAINE TO PRODUCE ANÆSTHESIA OF THE SKIN AND TISSUES BENEATH IT.

JACKSON, in the *Medical Record*, contributes an interesting paper on this subject.

From the first use of cocaine as a local anæsthetic the difference between its effects on mucous membrane and on skin was universally recognized. The probable reason for the difference is the greater thickness and horny character of the epidermis, which offers a sufficient obstacle to prevent the rapid absorption of the drug into the sensitive tissues beneath. The magnitude of this obstacle varies with the thickness of the epidermis in different parts of the body, it being greatest on the back and outer sides of the extremities and least on the inner surfaces, and particularly on and near the eyelids.

Probably better local anæsthesia can be obtained in the skin of the lids by the external application of cocaine than in any other part of the body. The application must, however, be sufficiently prolonged to allow of the soaking through of the epidermis by the fluid in which the drug is dissolved. While the various oils have been used to carry cocaine into contact with the tissue to be affected, they are of inferior value, probably because they do not give up the drug with sufficient rapidity to the serum of the tissues, and the watery solution gives better practical results. Its superiority has been very decided.

*Method of applying.*—Dropping the solution upon the surface is quite inefficient. In order to get the soaking of the epidermis necessary for the transmission of the drug, the surface must be kept moist for many minutes. This is readily accomplished by keeping it covered

with a pledget of absorbent cotton which is kept saturated with the solution.

The solution used should be as strong as possible, at least when it comes in contact with the tissue; if, however, the surrounding air is dry and the absorbent cotton is freely exposed to the air, the evaporation will readily bring even the weaker solutions of cocaine up to near the point of saturation.

A most serious obstacle to the necessary soaking of the epidermis is the presence in it of a considerable amount of fat. This may be removed by carefully washing with soap or other alkaline preparations. Yet this very precaution has probably been the cause of complete failure in many of the attempts to produce cocaine anæsthesia of the skin. The presence in the epidermis or upon its surface of any residuum of alkali leads to the precipitation of the alkaloid cocaine from the solution of its salts in a form that is quite insoluble, so that profuse washing of the skin to remove the fat may, by substituting the alkali, render it far more impervious to the anæsthetic than it was originally.

In practice this may be guarded against by the prolonged use of pure water to remove all traces of alkali.

Again, the fat may be removed from the skin by careful washing with ether, and this is the best means if sufficient time is not available for rather prolonged preparatory treatment.

It is probable that the general condition of the lymph-vessels materially influences the amount of the drug taken in through the epidermis. But to balance this, when absorption is most rapid into the skin, the removal of the drug from the point of introduction is also most rapid, so that the effect in anæsthesia obtained is not materially altered by the general condition of the lymphatics.

With the best application and under the most favorable circumstances the anæsthesia obtained by the application of cocaine to the surface is extremely superficial. Simply by such application, continued while the incision is slowly carried down from layer to layer of tissue, the incision can be gradually and painlessly extended to any desired depth. At least this is true of incisions that do not present so great a surface as to cause danger of cocaine-poisoning and are not made through inflamed tissue. But this process is an extremely slow one.

If the incision is to be carried at one stroke below the true skin, even in the thinnest portions the anæsthesia will not be deep enough to render it entirely painless, unless the cocaine

is also introduced hypodermically. To use it hypodermically with the best success, it is essential to bring the drug into direct contact with the tissue to be cut or injured, in the greatest degree of concentration practicable, to get it promptly diffused throughout this tissue, and then to complete the operation before time has elapsed to allow of its being carried off into the general circulation.

The author's method, then, of using cocaine upon the skin is first to prepare the surface, either by washing with ether or with an alkali, followed by prolonged rinsing with pure water; then to keep the surface covered with absorbent cotton saturated with a strong solution of cocaine for ten to twenty minutes. After that, for a rapid operation, to introduce the cocaine hypodermically directly into the tissue to be cut, rapidly secure its sufficient diffusion by massage, and then perform the operation within a very few minutes. Used in this way, cocaine is capable of very greatly lessening or entirely preventing the pain of the removal of tarsal tumors and even of dermoid cysts situated in the region of the lids or orbit. But it is always to be borne in mind that in the presence of hyperæmia and inflammation cocaine has little or no power as an anæsthetic.

#### CAMPHORATED CARBOLIC ACID AS AN ANTISEPTIC AGENT.

Toms contributes to the *Medical Record* a paper with this title, and in the course of it points out that it is very interesting to learn that that eminent surgeon,—“the father of antiseptic surgery,”—Sir Joseph Lister, has recently announced that he has returned to his first love,—carbolic acid. After these many years since his first employment of it for a definite purpose of prophylaxis against the entrance of germs to fresh wounds, and for antiseptic and germicidal purposes,—the birth of the “antiseptic” idea and theory,—after these years of painstaking clinical experiment and bacteriological research, it is at least remarkable that the first antiseptic, used as such, should now hold the first place in the favor of so careful an experimenter and observer as Lister. All those chemical agents which have enjoyed more or less confidence in their efficiency by authorities in surgery as “antiseptics” seem, after thorough testing of their merits, to have been found wanting. To be sure, the “antiseptic” theory has largely been supplanted by “aseptic” principles,—the natural evolution of the primary conception of the author; but there are many surgeons who,

while still having much confidence in carbolic acid, yet find very many and grave objections to its employment in a general way in surgical work, especially in private practice.

Its field of usefulness, although acknowledged by its most ardent employers to be perhaps greater than that of any other permanent and staple compound combining the essential antiseptic properties, would be still greater were it not for toxicity, odor, caustic action, etc. Its employment as a germicide, in strength sufficient to be effective against pyogenic bacteria and their spores, is fraught frequently with considerable danger, and often in an infected wound is not at all possible, excepting by a long and continued use in much reduced strength, in which nature plays the most important rôle, owing to its destructive effects on living tissue. As an antiseptic protective against the entrance of bacteria infecting a sterile wound through the dressings, it is questionable if it does not materially impair the integrity of healthy structures rather than act kindly in promoting the process of repair.

Recently the writer had occasion to resort to other means than the regulation dry dressings with dusting-powders—iodoform, aristol, dermatol, etc.—in treating an extensive ulcerating epithelioma whose surface covered about six hundred square centimetres of the leg. Amputation was out of the question, owing to the debility and age of the patient.

The odor, amounting to stench, the extreme irritability of the wound from exposed nerve-filaments, the deep points of ulceration, extensive absorbing surface, together with the profuse discharge, made up a condition that put his ingenuity to test. After employing "them all," together with antiseptic absorbent dressings, and almost despairing of ameliorating the sufferings of his patient or mitigating the condition in his home, his mind reverted to Lister's first choice and last resort,—carbolic acid,—in the hope that perhaps it could be utilized in some form to meet the indications in so appalling a case. Certainly carbolic acid possessed the ideal properties,—i.e., antiseptic, deodorant, and anæsthetic,—but its offensiveness was only second to that of the wound; besides, it would be required to employ it strong enough to check suppuration, in which strength it would be caustic or certainly irritating, while the extent of surface gave reason to fear possible absorption and development of toxic symptoms from prolonged use of the drug. Remembering a proprietary preparation which aims to be a fifty-five-per-cent. solution of

pure carbolic acid combined with camphor, and is stated by its manufacturers to be non-irritating, the caustic properties of the acid being destroyed, he concluded to try this on the wound of his patient.

Instead of using the proprietary article, he had a pharmacist make a small quantity after the formula of Bufalini, as given in the United States Dispensary, to see in what way it differed from the secret article. He found no difference whatever in appearance, excepting that the full-strength preparation was not irritating to the mucous membranes of the mouth, while the proprietary article was. He also had it made in the fifty-per-cent. combination, which differs only in strength from Bufalini's formula, and this was not found irritating to mucous surfaces. It is stated in the Dispensary that this preparation retains the full antiseptic and germicidal properties of the acid, without its destructive action to living tissue.

In the writer's case he diluted it with fifty per cent. of cotton-seed oil, applying it directly to the ulcer and covering it with sheet-cotton saturated with the same; over this was spread a dry antiseptic absorbing-pad made of powdered charcoal and antiseptic wood-wool, about half an inch thick, spread evenly between cheese-cloth gauze.

For cleansing purposes an irrigating solution was employed, composed of 1 to 1500 bichloride of mercury, combined with 3 to 1000 sulphate of copper, which he has found more effectual than the bichloride alone. After the accumulated secretions are fully washed away, the surface is sprayed with fifteen volumes peroxide of hydrogen, after which the application is made as described. He has been using this now for about three months in this case, with the happiest results,—perfect deodorization of the wound and lessening the formation of pus.

The patient is markedly more comfortable, the irritation has been allayed by the antiseptic and local anæsthetic properties of the remedy, and the extensive breaking down of tissue has been materially checked. Only one dressing is used in twenty-four hours, yet his freedom from pain enables him to comfortably sleep throughout the night, dispensing with the use of morphine, which he had been in the habit of taking, and requiring as a substitute a mixture of bromide, chloral, and hyoscyamus, in very moderate amounts. Moreover, the household are not continually nauseated by the all-pervading odor of the offensive discharges permeating the entire house. He has also employed this valuable antiseptic in recently lacerated wounds, and found in every

case healing promoted under one dressing by primary union.

A nice drain can be made by dipping sterilized candle-wicking into camphorated phenol. It is far superior to all forms of dusting-powders, in the fact that it is not decomposed by contact with the serum-albumin and liberating irritating elements to fresh wound surfaces, as in the case of the iodine derivatives. It keeps the wound moist, is absolutely unirritating,—on the contrary, is anæsthetic,—promoting the process of healing in the most kindly manner, and is the best protection we have against the entrance of bacteria. For this reason it is used to cover coeliotomy and other wounds where union by first intention is so desirable. He also believes it has positive therapeutic properties in dermatology.

---

ON THE INTERNAL ADMINISTRATION OF  
CALOMEL IN THE TREATMENT  
OF PSEUDO-MEMBRANOUS  
LARYNGITIS.

KOHN, in the *Medical Record*, highly recommends calomel in the treatment of true croup. He thinks that the remedy, which experience has shown to have the effect on the membrane of liquefying or softening it, is therefore the great desideratum; medicated steam inhalations (lactic acid, lime-water, turpentine) and sublimed calomel (Dillon Brown) have been given with this object in view.

Calomel administered internally, in the manner to be hereafter described, has seemed to have a satisfactory effect, and the results have been so gratifying that this method of treatment seems worthy of the highest commendation.

To a child under two and a half years .05 gramme of pure calomel is given hourly, sleeping and waking; for each year above two and a half years add .02 gramme of calomel to the hourly dose. A child of five years would, therefore, take .01 gramme of calomel every hour. The calomel must be absolutely pure and undeteriorated; it should be given without the admixture of sugar of milk or of any sugar whatever; it may be administered either floating on a teaspoonful of water, or, if the child refuses this because he knows it to be medicine, it may be given in milk, entirely unnoticed by the patient.

The case should be under the watchful care of a trained nurse, who must keep an accurate record, noting the slightest perceptible change in any of the characteristic signs. After one or two grammes of calomel have been given, a change in the laryngeal breathing sound should

be noticed. The treatment should and can be instituted at the earliest possible moment after the diagnosis is made.

The writer has given a child of two and a half years .06 gramme of calomel hourly until 4 grammes were taken; the patient recovered. To another child of three and a half years 5 grammes were given with success. A stimulating and supporting regimen to combat the sepsis was adhered to,—beef soup, white of egg, milk; Tokay wine or whiskey was administered at very frequent intervals.

The administration of nourishment and stimulants half-hourly to sustain the heart power is of the highest importance; everything given the little patient should be palatable and easily taken, as every struggle of the child against taking food or medicine increases the laryngeal stridor and perhaps causes the membrane to extend downward.

The use of mercury in plastic inflammation is one of the traditions of medicine: its praises have been sung by medical writers for more than a hundred years. Whether its so-called antiphlogistic properties are explicable by reason of its destructiveness of germ-life is not known. The action of calomel in croup, given as above described, bears out the old belief in actual experience. Under its use the stridor, the aphonia, the cough, in short, all the symptoms, slowly abate, showing that the membrane is gradually loosening its hold and becoming innocuous.

The advantages of calomel over sublimate are self-evident; the former is mild, non-irritating, can be taken for the necessary length of time without any other effect than a passing diarrhoea, perhaps, while the sublimate is a pronounced irritant poison, which, taken in frequent doses, will cause pronounced gastro-intestinal irritation, necessitating an interruption in the treatment at a critical period.

The powder of calomel of six centigrammes is small, tasteless, and easily administered to the most obstreperous child; not so with the bichloride mixture, when given hourly. If inunctions with blue ointment have been attended by the success claimed for them in diphtheria, then mercury absorbed into the circulation seems to have a controlling influence over the diphtheritic infection and its local manifestations.

For administration to children, calomel must be preferred to all other preparations of mercury, for reasons that are obvious. The danger of salivation is minimal; the writer has never seen a case of pyalism among children treated with calomel.

Severe diarrhoea has also been very rare. Three, four, or even five movements a day under the calomel therapy should be advantageous in this disease, provided the patient take nourishment; the sepsis is, to a certain degree, mitigated by the free action of the bowels.

Should the diarrhoea assume a severe or alarming character, the dose of calomel may be diminished, or the intervals between doses prolonged, or a starch injection, with or without a little paretic, may be given; and if the laryngeal obstruction seems to be lessening, the calomel should not be stopped altogether under any circumstances.

A very strong argument, from a pathological stand-point, in favor of the antiseptic treatment by calomel, or by mercury in any form, is found in the statistics and post-mortem examinations of Prudden and Northrup. In one hundred and fifty-one fatal cases, pneumonia was found in one hundred and four. In Northrup's article in "Keating," in eighty-seven cases, the larynx alone was affected in only one case; in another the membrane extended from the pharynx to the middle of the trachea; between this point and the bronchi of the fourth division nothing was to be found; from these to the finest bronchi, membrane was present; in thirty-four cases the membrane extended from the pharynx down to the finest bronchi. In view of this extensive growth of membrane, of what use can an inhalation be? The tidal air, which alone can carry the inhaled medicament, never reaches the finest bronchi; of what use, therefore, is any local treatment? The treatment by sublimed calomel (Dillon Brown) seems to be that which is advocated in this paper, but in a different form. It formerly was one of the methods of mercurializing a patient to volatilize calomel on a metal plate by means of an alcohol lamp. The treatment has the disadvantage of salivating the attendants of the child.

In mercury we have a drug which, absorbed into the circulation, would seem to have a specific effect on the membranous exudation of laryngeal diphtheria; and, of all its preparations, the mild chloride for administration to children is the best for easily bringing the system rapidly under its influence.

It is not claimed that recovery occurs in every case, nor is the writer in a position to bolster up assertions by statistics; favorable statistics would be accepted with incredulity any way. The simplicity of this method of treatment, ease of application, and the fact that treatment can be instituted the moment laryn-

geal stridor is noticed, in even the youngest child, are arguments in its favor.

Should the patient go from bad to worse, in spite of the treatment, and the symptoms assume a grave character, recourse can always be had to intubation or tracheotomy; and early operation, be it intubation or tracheotomy, Kohn believes should be decidedly discounted.

#### THE TREATMENT OF IMPETIGO.

In an article in *L'Union Médicale*, THIBERGE gives the following prescriptions for this affection:

R Vaseline,  $\mathfrak{z}\text{i}$ ;  
Boric acid, gr. xlv.

Or,

R Vaseline,  $\mathfrak{z}\text{i}$ ;  
Boric acid,  $\mathfrak{z}\text{ss}$ ;  
Oxide of zinc,  $\mathfrak{z}\text{ss}$ ;  
Salicylic acid, gr. vii.

He states that Besnier frequently employs the following ointment with advantage:

R Plaster of Vigo,  
Vaseline, of each, equal parts.

Dubreuilh recommends the following:

R Vaseline and lard, of each, equal parts;  
Oxide of zinc, gr. lxxv;  
Salicylic acid, gr. vii;  
Crystallized acetate of lead, gr. iii.

Vidal recommends the following:

R Simple cerate,  $\mathfrak{z}\text{i}$ ;  
Yellow precipitate, gr. x;  
Oil of cade,  $\text{m}\text{l}$ .

#### THE TREATMENT OF WHOOPING-COUGH WITH QUININE.

After sixteen years' experience in treating whooping-cough with all the usual remedies, DR. P. BARON writes (*Berliner Klinische Wochenschrift*, No. 48), warmly commending the use of quinine. He has used it in about fifty cases. Usually several days elapse before the improvement is marked, in part, no doubt, because much of the medicine is lost through vomiting. Sometimes its good effect is observed in two or three days. When once begun, the improvement makes rapid strides in decreasing the number and the severity of the attacks, even if the dose is diminished and given less frequently. He thinks a cure may be obtained, on an average, in six weeks. No relapse has ever come under his observation in

children cured of whooping-cough by the use of quinine.

But while unsurpassed for ordinary whooping-cough, the value of quinine is best appreciated when used for cases where acute affections of the lungs occur. Whether as an antipyretic or as a specific could not be determined, but its action was excellent. In one case, after but a few days' use of quinine, the relatives reported, beaming with joy, that the child, which was suffering with acute disease of the lung, demanded food and played, and that the fever had disappeared.

He cured three very severe cases with it. One was a delicate seven-year-old girl, sent from the city by the physician as a very last resort, hoping the change of air would benefit the whooping-cough. The child was daily growing worse. When Baron saw it, on June 18, there was a disseminated pneumonia, so severe that, in spite of his great faith in quinine, he felt no hope of its recovery. The child could not be prevailed upon to take the least nourishment, and the coughing prevented any sleep. As he believed quinine the only remedy, he tried to give the child three capsules, and was finally successful. At his next visit, on June 23, the child was sitting up in bed, and, although there were still dull places in the lungs, it was nearly free from fever, had some appetite, and was able to sleep some. The improvement continued from day to day, and no other remedy was required besides the quinine.

Another child was in a wretched, poor home, and had barely recovered from a long attack of inflammation of the lungs a year before. The whooping-cough was soon complicated with inflammation of the lungs. As soon as Baron gave the quinine the child improved, and, in spite of all the drawbacks, was well in three weeks' time.

Another child, three years old, had pneumonia with the whooping-cough, and was so reduced that both hands and feet had swollen. The action of the quinine was not so immediate here, but in three weeks the child was well.

No bad result from the quinine was ever noted. He thinks it should be determined whether it could be used as a prophylactic. The single dose is  $\frac{1}{6}$  grain of the hydrochlorate for each month, and  $1\frac{1}{2}$  grains for each year, of the child's age, given three times a day, preferably at 6 A.M. and at 2 and 10 P.M. Strong children require a larger dose, but a larger dose than  $6\frac{1}{2}$  grains to children over four years is generally not required.

#### USE OF HYDROGEN PEROXIDE IN THE PERITONEAL CAVITY.

In a very brief communication to the *New York Medical Record*, W. H. WIGGIN states that he has employed peroxide of hydrogen in full medicinal strength in cases in which, by accident or disease, pus has obtained entrance into the peritoneal cavity. He believes that this method is entirely without danger, and promises another communication upon the subject when his experience is larger.

#### A NEW AND RAPID METHOD OF ANÆSTHESIA.

DR. MAGILL, of Chicago, reports the following method of producing anæsthesia to the *Medical Record*:

The method was devised and developed, during the summer and fall of 1892, by Dr. Bourbon, anæsthetist of Hôpital Bichat, Dr. Hartman, acting surgeon, and Magill, and, since its introduction, is the preferred method in the surgical service of Professor Terrier, at Hôpital Bichat. The *modus operandi* cannot better be described briefly than is done by Professor Terrier in his communication on the subject to the Société de Chirurgie of Paris, October 19, 1892:

"The bromide of ethyl should be given in large doses. After pouring it abundantly [about 3 grammes] upon a folded towel, it is placed over the nose and mouth of the patient, who is told to breathe deeply. Generally at the second or third inhalation a slight agitation appears, but at the fifth or sixth the anæsthesia is complete, with total loss of consciousness. With the continuance of this anæsthetic, in a moment, sometimes preceded by tonic contracture, the complete muscular resolution is accomplished, with congested face and dilated pupil. At this moment the towel saturated with ethyl bromide is rejected, and another upon which chloroform is poured is substituted in its place, without allowing any interruption of anæsthesia in changing. The first dose of chloroform only should be fairly strong [1 gramme]. At this moment the operation may be commenced [about three-quarters to one minute since the commencement of the anæsthesia]. The facial congestion diminishes little by little, the pupillary dilatation gives place to retraction; in a word, the transition from the anæsthesia of the bromide to that of chloroform is accomplished without the slightest interruption of the sleep. From this moment the continuance of the anæsthesia is done in the ordinary way [chloroform in small and

regular doses]. The difference is simply that the complete anæsthesia is immediate, instead of resultant of a period often long, which is necessary in the process of chloroform anæsthesia." [And more so in case of employment of ether.]

The matter in brackets is not a part of Professor Terrier's communication, but inserted as explanatory.

It will be seen that the duration of the anæsthesia may be prolonged at the will of the operator. Experience has demonstrated that by this process a remarkably small quantity of anæsthetic agents suffices for complete and protracted unconsciousness, and that by reason of the smallness of the quantity used, the awakening of the patient almost immediately follows the cessation of administering chloroform.

The writer has performed a complete anæsthesia for ovariectomy by Professor Terrier with the administration of 3 grammes of ethyl bromide and 12 grammes of chloroform, recovery from sleep immediate, and no subnausea. Duration of the complete anæsthesia thirty-two minutes.

This is only one of many similar cases which will be found in the publication of the clinical studies. How many anæsthetists are there who can obtain a complete resolution of a vigorous subject with 12 grammes of chloroform only?

The advantages claimed for this method are,—

1. Rapidity, a complete anæsthesia, which allows the commencement of the operation in one minute's time after the first inhalation of the anæsthetic.

2. Doing away with all violent agitation on the part of the patient, so common when chloroform or ether alone is used.

3. On account of the dissimilar physiological action of the two anæsthetics employed, the dangers attributed to the use of chloroform alone are in a great measure eliminated by the counteraction of the ethyl bromide previously administered.

4. An almost entire absence of post-operative nausea.

In February of this year this method was introduced in the service of Dr. Segond, at the Maison de Santé, the City Hospital of Paris, by Dr. Malherbe, and immediately adopted by Dr. Segond for all of his work, to the exclusion of other methods. It was the writer's privilege to introduce this method in the service of Dr. Monod, at Hôpital St. Antoine, in April of this year, which led to its adoption as the current method throughout his wards. Dr. Riche-

lot, of Hôpital St. Louis, has spoken with considerable favor of this process of anæsthesia in the discussion at the Société de Chirurgie, and employs it in his service in preference to all others in cases where affections of the heart cause any apprehension from the use of chloroform alone.

The patients who have been subjected to this method of anæsthesia have pronounced in its favor, and in cases of an anæsthesia to be repeated for them have asked for this method.

In a short time a monograph on the subject, with complete bibliography, chemical and physiological aspects, and several hundred detailed clinical studies of its application, will be published in Paris as a complete history and introduction of the subject. There appears to be no element of danger in the combined employment of these two agents for a complete anæsthesia, and the simplicity of its application will be evident on trial.

---

#### NOTE ON THE EMPLOYMENT OF CALCIUM CHLORIDE AS A HÆMOSTATIC.

SAUNDBY, in the *Birmingham Medical Review*, contributes a short note upon this subject, basing his experience upon the experimental report of Professor Wright. The three following cases are therefore of interest:

The first of these was a middle-aged woman, with chronic jaundice of six months' duration, believed to be due to an impacted gall-stone. She suffered from pretty free hemorrhage from the rectum, apparently proceeding from some internal piles, but the bleeding was decidedly more than we should have expected from the state of the bowel. Our first efforts were directed to remove the hard fæces which could be felt in the rectum by the use of olive-oil injections, and to keep up a daily action of the bowels by the administration of saline aperients; but as after fifteen days these means failed to check the bleeding, calcium chloride in small doses was administered every four hours, with the satisfactory result that after five days the hemorrhage ceased and did not return.

The next case was even more striking, as it was that of an elderly woman, admitted with purpura hemorrhagica,—that is to say, she had a purpuric rash over the body and limbs, free bleeding from the gums, and slight hæmaturia. The free use of ergot, gallic acid, and acid infusion of roses not having been followed by any benefit, on the third day after admission she was placed upon small doses of calcium chloride every two hours, after which the bleeding di-

minated, and five days later had ceased altogether, the patient making a good recovery.

In the third case, which was one of phthisical hæmoptysis, calcium chloride was used in combination with other measures, but, in spite of all treatment, a profuse hemorrhage set in which carried off the patient. At the autopsy we found an aneurism of the pulmonary artery projecting into a cavity, a condition which sufficiently explained the futility of our remedies.

With respect to dose, it is noteworthy that Professor Wright found, after giving 1 gramme thrice daily for four days, that the coagulability became enormously diminished,—i.e., to over one hour,—and on certain experiments upon himself he believes this was due to the administration of calcium chloride having been carried too far, for he found that when too large a dose of the salt was added to decalcified blood *in vitro*, coagulability decreased, and on taking 2 grammes of calcium chloride three times a day the coagulability of his blood rose during the first twenty-four hours, returned to normal during the second, and in the third fell below normal, so that the best results may be looked for from comparatively small doses. In the author's cases the drug was administered in the form of the liquor calcii chloridi of the new British Pharmacopœia, which is of the strength of 1 to 5, and the dose employed never exceeded 30 minims, or 6 grains, though in the case of purpura this quantity was given every two hours during the day for some days.

---

NOTE ON THE TREATMENT OF WARTS  
BY THE INTERNAL ADMINISTRATION OF ARSENIC.

SYMPSON contributes an article on this subject in the *Quarterly Medical Journal*.

Though warts sometimes disappear spontaneously without any treatment whatever, and although the treatment of them by various kinds of outward applications is often perfectly successful, yet quite enough cases are found apparently intractable by ordinary methods to justify a short note on the use of a drug which seems specially adapted to cure this tiresome and vexatious complaint.

First a word or two as to local remedies. The writer has tried on different patients, and occasionally the same patients, nearly all the drugs usually recommended for the abolition of warts. Such are glacial acetic acid, salicylic colloid, fuming nitric acid, carbolic acid, liquor potassæ, and argenti nitras. The first two named in this list seemed to act best, and

the salicylic colloid he prefers of the two, as most easily applied by any unskilled person and least irritating to the patient.

But for the last few years, acting on a suggestion in an American medical journal, and on account of Mr. Pullen's paper (*Practitioner*, 1888, vol. i. p. 207), in every case of warts which did not show some sign of yielding to these applications in ten days or a fortnight, he prescribed small doses of arsenic internally. Of its rapid action on the warts there can be no doubt whatever. He has repeatedly tried it by itself, and by the end of a fortnight even a large crop of warts will have disappeared. An advantage also of its use alone is that by children (who are, of course, the chief sufferers from warts) any kind of caustic or painful application is much dreaded; also very little arsenic need be given. The drug need not always be given as long as a fortnight, for a week's treatment by small doses twice a day seems to set up a healthy action in the warts, which is continued after the medicine has been left off. The combined treatment, though, of arsenic internally, with salicylic colloid painted daily on the warts, is quicker than that by arsenic alone. The author gives 1, 2, or 3 minims either of the liquor arsenicalis or liq. arsenici hydrochlor. twice or three times a day, according to the age of the child, and has never found it needful to exceed the largest dose. He has never found any symptoms of its disagreeing with the patients.

Its action on the warty growth is no doubt due to the increased metabolism of the skin, leading to these hypertrophied portions being killed and exfoliated.

It is somewhat curious to note that arsenic has been accused of producing warts.

---

A SHORT CRITICAL ANALYSIS OF TWENTY-SEVEN CASES OF TETANUS TREATED WITH SERUM OR TETANUS ANTI-TOXIN.

BEHRING and KITASATO (*Deutsche Med. Wochenschrift*, 1893, pp. 152-154), through the most brilliant researches, have shown us by what therapeutic measures we may hope to overcome the most deadly of infective diseases. Tizzoni and Cattani, in Italy, and Roux and Vaillard, in France, followed closely in their footsteps. Of all microbic diseases, the most hopeless to treat or prevent was tetanus. Animal experiments, however, have shown that by means of injections of serum obtained from immunized animals it is possible not only to protect animals against tetanus, but also to

cure those which already suffer. Those experiments were soon applied to man, especially in Italy, and a small number of cases is already on record. It may not be out of place in the present journal to put these cases together and see what lessons have been learnt from them. We may say at once that though it will be found that so far the treatment has been of little benefit in really serious cases, that, nevertheless, the serum treatment is at present the only rational treatment to be employed. Our English laboratories, unfortunately, cannot supply the precious substance. Roux and Vaillard, however, are always ready, with the courtesy characteristic of the Institute Pasteur, to supply hospitals with the serum; and, so long as the latter is not procurable in our country, we advise surgeons to apply at the institute, so that they may have the serum ready in an emergency, instead of losing time when they are brought face to face with a case.

Eleven cases have been treated by antitoxin obtained from Tizzoni and Cattani, of Bologna, and none of these have ended fatally, and on the strength of this result the Italian school considers the curative action of the serum as proved. The antitoxin is practically nothing but serum; it consists of the alcohol precipitate of immunizing serum, and we shall not draw any distinction between serum and antitoxin, especially since latterly Tizzoni has used both the serum and antitoxin in the same cases. On looking into the Italian cases we find, however, that they were all of a mild type, as pointed out by Rotter and Roux and Vaillard. The last case, published recently in the *Centralblatt für Bact.*, at first sight is more acute or malignant, but on closer inspection one may really doubt whether it was the serum and antitoxin which cured. The temperature in this case was never raised, and after the first injections the symptoms did not abate. Taking them altogether, we must confess that these eleven cases were more or less benign, and here the antitoxin treatment did good. In most cases, with three exceptions, the incubation period extended over ten or more days, and in almost all of them the treatment was not begun until two or three weeks after the primary injury; and though a cure resulted in some cases after a few days, in most cases this did not take place until six to twelve days after the first injection. A case such as this, for instance, is quoted as a successful one by Finotti. The disease began twenty-four days after the injury; injections were begun five days later, and continued until the forty-second day. The

severest case so far treated by Tizzoni, as we mentioned just now, is the eleventh, where tetanic symptoms appeared on the sixth day, and treatment was commenced almost immediately and carried on for five days, when the patient was practically out of danger, though the tetanic seizures did not entirely disappear until the sixteenth day after the injury. We do not wish to detract from the merits of these cases, all the less as we are advocates of the new treatment, but it is our duty to weigh all points and not to raise false hopes. These eleven cases cannot prove much either for or against the usefulness of the antitoxic serum as a curative agent. How true this is will become clear if our readers be reminded that it seems that only the successful cases have been published by the Italians. We can hardly understand such a secrecy and misapplied reticence in this country. Rotter mentions three fatal cases of which he has heard, and Albertoni, as well as Roux and Vaillard, refer to the culpable suppression of fatal cases treated by Tizzoni's method.

If we now glance over the cases of tetanus treated by serum obtained from Behring, we find, again, that in acute or severe cases the result has hardly been satisfactory. We have succeeded in collecting six cases. Of these, four survived, but none of them were really severe. Rotter, for instance, who relates one case, never feared for his. Moritz's case was serious, but chronic, and the other two were unquestionably mild. Of the two fatal ones, we must, in all fairness, exclude the case treated by Baginsky and Kitasato, since here only a very small dose of serum was administered, and in the other fatal case it seems that the serum was not so strong as might have been wished. Any way, it will be seen that from these six cases a just conclusion as to the efficiency of the curative serum in tetanus, as we are likely to meet it in hospital practice, cannot be drawn. We realize this still more on studying the cases published by Renon and Roux and Vaillard. Renon's two cases both ended fatally. They were treated with rabbit's serum, but we find no data as to the efficacy of the serum, etc. Of these, we must again exclude one,—a successful one,—since here the tetanic seizures ceased after the amputation of the injured finger, and, besides, the quantity of serum injected was so small that we can hardly believe that it had any effect on the course of the disease. They relate two other successful cases, but say themselves that "à aucun moment ces deux malades n'ont donné de sérieuses inquiétudes." On the other hand, five acute and

severe cases, treated as early as possible with large quantities of very active serum, were not benefited in the slightest degree.

Taking all the twenty-seven cases, then, without critical analysis, we find that of twenty-seven cases to which serum was given, nine died. To these we ought to add at least three, if not more, which have been suppressed, so that of thirty cases, twelve were fatal. Now, what is the percentage of deaths in cases of tetanus treated on ordinary hospital principles? Behring would make us believe that eighty to ninety per cent. of all cases are fatal, while Albertoni's figure is twenty-four, Sormanni estimating it at forty-four. According to Roux and Vaillard, fifty most likely represents the correct percentage in our modern antiseptic days, and if this be so, we find that the thirty cases treated with serum have not been accompanied by sufficient success to warrant us in giving a favorable prognosis in those cases which have been treated with antitoxin serum. But are we, therefore, to give up this method of treatment? By no means. We must confess, with Roux and Vaillard, that in the rapid form of tetanus the serum treatment has been powerless, and has not in the slightest degree modified the course of the disease. But in practice we cannot choose either case or opportunity, and our remedies must be employed under the conditions as they exist. However, all cases, successful or fatal, should be published, so that we may learn what we are entitled to expect from the antitoxic treatment. At present it seems that in severe and rapid cases of tetanus the prognosis is as bad as ever, and Roux and Vaillard found that this is true also for tetanus artificially produced in animals, for they say that in animals "le traitement a échoué dans les tetanos graves." It may be that we require more active serum than it has so far been possible to obtain. The French authors give what seems to us to be sound advice,—viz., to use the serum as a preventive measure in contused and dirty wounds, either in hospital practice or on the battle-field, and in such cases where there is a possibility of tetanus setting in. Tetanus is a rare disease, but many who are seized by it are doomed to die a miserable death. A small dose will suffice to prevent, while a cure may be impossible with large doses. Why, therefore, not attempt prevention, especially when it is so easy to procure the serum in a suitable form from the Institut Pasteur? We again urge on all hospitals the necessity of providing for themselves a suitable quantity of the antitoxic serum, and we only regret that there should be no laboratory

in England capable of supplying what our brethren across the silver streak liberally offer us.—*Medical Chronicle*, vol. xix., No. 1.

#### ESERINE IN THE LOCAL THERAPEUTICS OF IRITIS.

HANSELL (*Philadelphia Polyclinic*, January 20, 1894) calls attention to the occasional danger of prolonging the use of atropine in cases of iritis, especially of such variety where there has been abundant exudation, and recommends a solution of eserine strong enough to break off the capsular attachments, but weak enough to avoid undue excitement of the ciliary structures. He has found disks each containing 1000 grain convenient. The effects of the drug must be carefully watched, for if it is too strong, or too frequently repeated, a relapse of the iritis may be expected.

#### A MODIFIED OPERATION FOR EXTRACTION OF CATARACT.

T. E'GAPPA (*Indian Medical Gazette*, December, 1893) lacerates the capsule of the lens as the first step in the operation for extraction of cataract. He believes the best part of the cornea at which to insert the needle is from two to three millimetres above and to the inner side of the outer extremity of the horizontal diameters of the cornea. The pupil is fully dilated and the incision is a crucial one. The lens is then extracted through an ordinary corneal incision, and usually without iridectomy.

#### THE ACTION OF CARBONIC OXIDE ON THE EYE.

M. SCHMITZ (abstract of original paper published in the *Annales d'Oculistique*, November, 1893) observed ocular disturbances in two cases of severe poisoning by carbonic oxide. The first patient was unconscious for twenty-four hours, and paralyzed in his limbs for three days. On the fourth day vision equalled one-sixth; there was intense photophobia, and later the field of vision was contracted; all colors were distinguished at the fixation point. Gradually the symptoms improved until the end of the fifth month, when they were normal. Ophthalmoscopically the veins were distended and the arteries contracted. After the accident there was anæsthesia in both hands and both forearms. In the second case there was also concentric contraction of the visual fields and diminution of central acuity, but the symptoms varied considerably at different examinations. There was also anæsthesia of various portions

of the skin of the body. The author believes that in both cases he dealt with a form of toxic hysteria.

*THE EMPLOYMENT OF INJECTIONS OF  
ORGANIC EXTRACTS IN THE TREAT-  
MENT OF DIFFERENT FORMS  
OF ATROPHY OF THE  
OPTIC NERVE.*

BOURGON (*Annales d'Oculistique*, November, 1893), after referring to the article of Galtier on the treatment of gray atrophy of the optic nerve by the injection of organic extracts, in which he had apparently seen a good result, details four observations of his own,—the first, a case of white atrophy, probably of intracranial origin; the second, one of atrophy in a tabetic patient; the third, also intracranial in origin; and the fourth, of uncertain origin, perhaps diabetic. The interesting point of the report is that, although one of the patients was undoubtedly tabetic, and the doses of the liquid employed were very considerable, the results were absolutely negative, and, therefore, he doubts any efficacy in the Brown-Sequard method in so far as optic atrophy is concerned. He mentions, in passing, that he has had better results in two cases by the use of antipyrin, as recommended by Valude, than by any other medicament.

*CLINICAL RESEARCHES ON PARALYSIS  
OF THE OCULAR MUSCLES, AND  
THEIR TREATMENT.*

DR. J. D. MELLO VIANNA (Paris Thesis, 1893) has published a brochure on this subject, and the following abstract of the chapter on treatment appears in the *Archives d'Ophthalmologie*, November, 1893:

When syphilis has been established, or is only suspected, and even where the etiology is uncertain, the treatment should begin with mercury, preferably the hypodermic method, which may be safely employed if rigorous antisepsis is practised. The formula of Professor Panas follows:

R Biniiodide of mercury, .40 centigramme;  
\* Sterilized water, 100 grammes.

The injections should be made with a carefully sterilized Pravaz syringe, and the area selected for puncture should also be properly disinfected. The injections should be intramuscular, and the needle made to penetrate some depth into the tissues. The region of the buttock is preferred.

The formula of De Wecker is also given as follows:

R Corrosive sublimate, 1 gramme;  
Chloride of sodium, 2 grammes;  
Acetate of morphine, .40 centigrammes;  
Distilled water, 100 grammes.

A Pravaz syringe contains about 1 centigramme of sublimate. The dose is one injection per day.

*TENOTOMY OF THE OCULAR MUSCLES.*

An editorial in the *Medical News*, after referring to the fact that in the Ophthalmic Section of the Pan-American Medical Congress there was a manifest inclination, with a few exceptions, towards a more conservative and therefore medical treatment of heterophoria, proceeds as follows:

It is also fast coming to recognition that, owing to the very peculiar and complex interrelations and functions of the ocular muscles, as well as from a hundred other reasons, these muscle-troubles, supposed and so-called, are often not muscle-troubles at all; they are not always peripheral in origin or in essence, but are often of central origin. The malfunction resides in the innervation and the innervating centres. For example, upon a patient with eighteen degrees of esophoria, complete tenotomies of both internal creti have produced temporary muscle-balance, but in ten days the eighteen degrees reappeared, and the man stood just where he was before the operation.

In the first place, many of these inco-ordinations are due to general disease, such as anæmia, tabes, pelvic disorder, syphilis, etc., and require proper general treatment to re-establish healthful normality of function. One of the speakers of the Congress detailed a number of cases that had come under his observation, in which operations on the muscles had been worse than useless, because the paresis was plainly due to cord-disease.

Then, again, a large number of these inco-ordinations are due to the uncorrected ametropia. The tenotomist, despite himself and despite his remonstrance, ignores the fact or depreciates its importance, that the refractive error produces muscular defect, and the correction of the ametropia either relieves the reflex symptoms or cures the muscular unbalance. It is perfectly possible, nay, it is highly probable, that hyperopia and hyperopic astigmatism may be the chief etiological factors in the production of *both* esophoria and exophoria. A single cause may produce diametrically opposite results, according to its strength and according to the circumstances and conditions among which it operates.

Finally, in a large balance of cases not due to general disease, or to ametropia, it is certain that gymnastic exercises may re-establish the desired muscular equilibrium. All success by this method depends upon the kind of exercise and how it is carried out. In the case of other paretic muscles,—supposing, for argument's sake, that the muscles are primarily at fault,—we do not cut them, but we endeavor to stimulate them to healthy action and development by gymnastics, by hygienic and physiological measures. Why not also do the same with the muscles of the eye?

There is a proper place for tenotomy for insufficiency, but it should be resorted to only after the foregoing methods have been tried.

#### ON CERTAIN DANGERS ATTENDING THE USE OF ATROPINE AND THE EMPLOYMENT OF SCOPOLAMIN.

DR. HASKETT DERBY (*Boston Medical and Surgical Journal*, December 28, 1893), after calling attention to the well-known dangers of atropine and its power to precipitate an attack of glaucoma, as well as produce severe constitutional disturbances, refers to scopolamin originally introduced by Raehlmann. He quotes some observations with this drug made by Dr. Haskell of the Massachusetts Charitable Eye and Ear Infirmary, a one-fifth-per-cent. solution of the drug having been used in seven cases. The first column gives the age, the second the number of minutes that elapsed before any effect was perceptible, the third the minutes required for maximum dilatation, and the last the number of hours that elapsed before the pupil again became normal.

9	8	40	51
8	16	35	60
17	10	21	72
12	9	30	80
9	10	25	60
20	10	20	80
12	12	40	90

Raehlmann's conclusions, already abstracted in the columns of the *GAZETTE*, are quoted, and Derby thinks that if further experience corroborates them, it is likely that scopolamin may supersede atropine.

#### THE EYE TREATMENT OF EPILEPTICS.

DR. AMBROSE L. RANNEY, (*New York Medical Journal*, January 20, 1894), comes to the following conclusions as the result of his observations on the eyes of epileptics:

1. In epilepsy he regards an examination of the eyes (for errors of refraction) and of the eye muscles (for heterophoria) as the first and perhaps the most important step towards a search for sources of reflex nervous disturbance.

2. No final conclusion should be reached regarding the presence or absence of heterophoria until sufficient time, patience, and skill have been bestowed upon the investigation by one who is thoroughly familiar with the practices and later methods for the determination of "latent" heterophoria.

3. All preparations of bromides and other drugs that tend to control the seizures should be withheld, as a rule, from an epileptic patient until all possible sources of reflex irritation have been scientifically sought for and, as far as possible, relieved.

There may be justifiable reasons, to his mind, for exceptional departures from this rule; but he wishes to emphatically raise his voice in protest against the prevalent system of drug-ging epileptic patients from the date of the appearance of the first fit without any attempts being made to ascertain what the cause of the epilepsy may be.

4. He strongly advocates the employment of atropine in every case before a final decision is reached regarding the refraction of an eye.

He also believes that in epileptic cases it is wise to insure a full correction of any existing astigmatism (by glasses to be worn constantly in well-fitted spectacle-frames), and as near a full correction by spherical glasses of any latent hypermetropia that is detected as the patient can be made to tolerate, even if atropine has to be instilled at intervals into the eyes of the patients for several weeks to prevent a return of ciliary spasm.

He has observed many cases of chronic epilepsy that have been relieved of all convulsive seizures so long as the full effect of atropine upon the ciliary muscle was maintained.

5. No promises that absolute cure can be effected by eye treatment should ever be made to an epileptic; but it is usually safe for the physician and patient to hope that a radical correction of marked heterophoria and abnormal refraction will eventually be followed by decided and permanent benefits.

6. The results in all cases thus far treated by him seem to warrant the conclusion that at least ninety per cent. of chronic epileptics have been better without bromides, after a satisfactory correction of their eye defects, than they ever were when subjected to the influence of drugs. Some have apparently been cured.

It should be remembered that a victim to

chronic epilepsy who is rendered by any treatment as free from the attacks without the bromides as when under their deleterious influence has been very markedly benefited; again, that if a marked diminution of the attacks has been effected, the patient has double cause for gratitude; finally, that if the attacks are arrested *in toto* without drugs, it is to-day one of the most remarkable facts recorded in medical literature.

7. In cases where negative results have been observed in spite of a satisfactory investigation and correction of marked heterophoria and abnormalities of refraction, he would deem it wise before resorting to drugs for epileptic seizures to search for other sources of reflex peripheral irritation (such, for example, as bad teeth, phimosis, rectal or uterine disease, scars, etc.).

Furthermore, the detection of chronic kidney disease, syphilis, organic brain lesions, and depression of the skull is most important prior to the beginning of eye treatment or a search for other forms of peripheral reflex disturbances.

8. The treatment of heterophoria by prismatic glasses alone is not curative; nor, in his opinion, are very marked beneficial results to be expected from them. Prismatic glasses are valuable aids, however, in determining the existence and amount of "latent" heterophoria prior to the radical correction of such defects by graduated tenotomies.

#### THE TREATMENT OF ULCERS OF THE CORNEA BY CURETTING ("RACLAGE") AND ANTISEPTICS.

FROMAGET (*Annales d'Oculistique*, October, 1893), communicated a paper on this subject to the Society of Ophthalmology of Bordeaux, and comes to the following conclusions:

Raclage, with antiseptic irrigation and dressing, is indicated,—

1. In persistent phlyctenular or traumatic ulcers which, accompanied by intense reactionary symptoms, have no tendency to heal or induce infection.

2. In asthenic ulcers.

3. In infectious ulcers of small volume.

It is useless and consequently not indicated:

1. In recent and superficial ulcers when there is no infection.

2. In ulcers of granular conjunctivitis.

3. In infectious ulcers of large volume with infiltration of the cornea.

It is necessary to combine paracentesis of the cornea with raclage in the following cases:

1. Increased depth of the anterior chamber and rise of the intraocular tension.
2. Danger of perforation.
3. Existence of obstinate hypopyon.

#### ON THE ACTION OF ELECTROLYSIS UPON THE DEVELOPMENT OF STAPHYLOCOCCUS AND STREPTOCOCCUS.

VALUDE (*Annales d'Oculistique*, October, 1893) makes the following abstract of an article with the above title published by Lagrange. Inasmuch as electrolysis is used to cure dacryocystitis, it was sought to determine the influence of this electrical action on the micro-organisms which multiply in the lachrymal ducts and are the first cause of dacryocystitis. The experiences of Lagrange have shown him that electrolysis possesses a definite microbicidal action. If the micro-organisms are not absolutely destroyed, their virulence is greatly lessened. The author thinks that the bactericidal action is due to the chemical electrolytic decomposition and to the direct influences of the gases thus produced upon the micro-organisms. It is known, indeed, that electrolysis of the lachrymal ducts is accompanied by the production of an abundant foam. The gases thus developed act powerfully upon the vitality of pathogenic agents.

#### THE TREATMENT OF EPIPHORA.

VALUDE (*Annales d'Oculistique*, October, 1893) submits the following abstract of a paper published by Bettremieux (*Journal d'Oculistique du Nord*, February, 1893): In stubborn epiphora, instead of attacking the principal or accessory lachrymal glands, as is now usually done, Bettremieux performs galvano-cauterization of the excretory ducts of the lachrymal glands at their openings into the conjunctival cul-de-sac, so that the former become obliterated and the epiphora ceases. This is his method of procedure: After cocaine-ization, the superior eyelid being quite reversed, the patient looking downward and inward, he performs a number of superficial puncture cauterizations on the surface of the palpebral lachrymal gland situated in the external part of the upper cul-de-sac of the conjunctiva. The patient feels no pain at the time of cauterization, and later suffers very little or not at all. Sometimes a slight localized conjunctival injection is produced, with scarcely ever any swelling. These cauterizations should be made repeatedly at intervals of several days. According to the author, the cicatricial pro-

cesses which are thus induced ought to cause obstruction or, at the very least, contraction of a certain number of excretory ducts of the lachrymal gland. Although it is not possible to touch with the point of the platinum needle repeatedly and unerringly upon the openings of these canals, it is reasonable to admit that the cauterization of the portion of the cul-de-sac corresponding to the seat of the excretory duct ought to be an obstacle to the flow of the lachrymal fluid, and to determine secondarily a certain atrophy of the gland as may in reality be produced after accidental cauterization, or in consequence of the cicatricial lesions which follow certain types of granular or diphtheritic conjunctivitis.

#### A NEW TREATMENT OF GLAUCOMA.

KNISS (*Annales d'Oculistique*, August, 1893) succeeded in checking glaucomatous accidents by making a circular incision in the cornea and including the iris in it. This irido-sclerotomy proves useful, especially in severe forms of glaucoma. Hernia of the iris, always to be dreaded in ordinary sclerotomy, is thus avoided. This operation may be recommended in all cases where iridectomy would have been deemed necessary.

#### THE ABUSES OF COCAINE IN NASAL TREATMENT.

A good note of warning and sharp criticism was read on this subject by WILKINSON, of Omaha, at the Milwaukee meeting of the American Medical Association, and is published in the *Journal* of November 25. His strictures are too largely directed to the employment of the drug in various proprietary "catarrh snuffs," and might well have been extended to its medical employment. The numerous, and already sometimes disastrous, cases of the formation of the cocaine habit which had fallen under his notice prompted him to his suggestion that medical men should unite to combat promptly and vigorously this growing evil, and to secure legislative bars to the vending of such preparations. His protest might have been applied with nearly equal force to the undue use, and still more to the prescribing, of cocaine by the profession. It has from the first been a matter of real surprise that a drug of such potency had not more of deleterious effect; but he who has used it much and seen no bad results speaks ill for his observation. Close and conscientious observers have almost always learned to be increasingly cautious in their own use of it, and have often wholly forsworn

giving it into the hands of a patient. Its great value in the investigation and treatment of nasal troubles will always make it tempting to resort to its use more often than is best, and it is well that those who are continually seeing its dangers and actual damage should insist upon an employment of it as limited and cautious as is or ought to be the rule as to morphine.

#### COCAINE-POISONING: REPORT OF A CASE WITH ALARMING SYMPTOMS.

DR. ALBERT R. BAKER (*American Journal of Ophthalmology*, November, 1893) reports a case of operation upon the nasal duct under the influence of cocaine, with the symptoms which follow: Preparatory to slitting the canaliculus, he instilled into the eyes two drops of a six-per-cent. solution of cocaine, which he had used the morning of the same day without accident upon a boy about twelve years of age. After waiting two or three minutes, the canaliculus was slit and three drops injected into the lachrymal sac. He then attempted to pass a lachrymal probe, but as the patient still complained of pain, three more drops were injected, making eight in all. Almost instantly the patient complained of feeling queer and commenced to talk incoherently, soon becoming unconscious, and developing clonic convulsions of all the extremities. Respiration was frequent and sighing. The face was flushed, the pulse accelerated, irregular, varying from 120 to 50 a minute, but at no time very weak. The convulsions lasted for over two hours. Inhalations of ammonia, and later on of nitrite of amyl, were tried without apparent benefit. A hypodermic injection of brandy was also given. As the patient emerged from the unconscious condition she became slightly delirious, requiring the constant services of two or three attendants to prevent injury to herself or to others. Her mind was filled with the most extravagant hallucinations, in many respects resembling those produced with *duboisia* or *cannabis indica*. At one time she would see many objects on the floor; at another be sewing, and then she would imagine bodily harm, all the time talking and gesticulating as vehemently as in acute mania. These symptoms continued for about six or eight hours, and were so persistent and violent that he did not feel justified in removing her from the office before ten o'clock in the evening. She slept but little during the night, but was recovered in the morning. As soon as she could swallow, aromatic spirits of ammonia were given, and strong coffee

inhalations of ether were tried sparingly to control the violent maniacal symptoms. It is possible, in Dr. Baker's estimation, that more heroic use of these remedies, or a hypodermic injection of morphine might have allayed the very embarrassing symptoms. One of the most persistent hallucinations of this patient was that she was being delayed for improper purposes, although no definite erotic symptoms were evident, such as have been reported by Richardson in one case. Dr. Baker's paper concludes with a partial analysis of cases of cocaine-poisoning, and particularly those which have resulted in death.

#### THE TREATMENT OF PURULENT (GONOCOCCAL) CONJUNCTIVITIS.

BURCHARDT (*Centralbl. f. Prakt. Augenheilk.*, November, 1893) does not believe in the use of cold compresses and cauterization of the mucous membrane with strong solutions of nitrate of silver, but advocates the frequent irrigation (sterilization) of the conjunctival cul-de-sac. For this purpose he uses a one-sixth-per-cent. or one-tenth-per-cent. solution of nitrate of silver. If there is much pus, he first irrigates with a five-per-cent. solution of aqua chlorinata, and follows this with the nitrate of silver.

#### SINGLE-SUTURE OPERATION FOR ADVANCING THE RECTUS.

DR. A. E. PRINCE (*Archives of Ophthalmology*, October, 1893), after referring to his well-known paper on double-suture operation for advancing the rectus muscle, together with the single-suture method for accomplishing the same purpose, describes the latter operation a second time and more completely. The following indications must be fulfilled:

1. Secure an unyielding anterior fixation point in line with the muscle to be advanced by utilizing the dense episcleral tissue.

2. Secure the muscle in such manner that its escape and retraction may not occur after the tendon has been excised and the muscle released from the grasp of the advancement forceps.

3. Secure the suture with such a knot as will permit of its being loosened for the purpose of increasing or diminishing the tension or the introduction of another suture farther back. The method is as follows: The conjunctival incision is made over and parallel to the attachment of the tendon of the muscle to be advanced. The tendon is secured by an advancement forceps, separated from the sclera,

and advanced, allowing the conjunctiva to retract. Two slender eye-needles on either end of a No. 3 iron-dyed silk suture are passed from within outward, perforating the capsule, muscle, and conjunctiva at a variable point, depending upon the amount of displacement to be effected, thus securing the middle portion of the muscle in a sling from which it can neither slip nor escape. With the exception of cases requiring a small amount of advancement at the muscle, or those in which the suture is used as a control to prevent an over-correction following a tenotomy, the portion of the tendon in the grasp of the forceps is excised about two millimetres anterior to the sling. The sclera being now fixed, preferably with Critchett's short fixation forceps, an unyielding anchorage in the form of a fibrous pulley is secured in the line with the rectus by introducing either needle into the dense episcleral tissue two millimetres from the corneoscleral junction. Both ends of the suture are now brought together, forming the first portion of a surgical knot, and tied to effect the slight over-correction. This may now be secured or provisionally held by the application of a bow until muscular tonicity shall have returned, thus enabling the effect to be modified at any time before adhesion has taken place. The suture is permitted to remain four days, unless it is desired to diminish the effect, which may safely be done after forty-eight hours by removing the suture and cautiously opening the wound.

#### OPERATIVE TREATMENT OF THROMBOSIS OF THE LATERAL SINUS.

A noteworthy communication upon this important topic was made to the Otological Section of the British Medical Association by ARBUTHNOT LANE, as reported in the *Brit. Med. Journ.*, No. 1706. He reports ten cases with nine recoveries, in which he laid open the sinus, ligated the internal jugular in the neck below any thrombus there encountered, and irrigated thoroughly the suppurating surfaces. This operation, which is generally accredited to the suggestion of Victor Horsley, although advised by Zaufal in 1880, has been practised with varying results by a number of surgeons, general and special, several of the successes having been very brilliant. No such group has hitherto been reported by one operator, and his results are likely to bring it into more favorable notice and more frequent employment by the general surgeon. It is, therefore, very fitting to direct attention to the long recognition of these cases and their fairly suc-

cessful treatment by the aural surgeon, as witness the publications of Schwartz, Hecke, Moos, and a number of others who have encountered instances of the affection apparently more severe than those of Lane, and brought an equal proportion of them to as speedy and perfect healing by simple mastoid trephining, or at times without any operation. Those also who have been less fortunate, and have secured autopsies upon their cases, have found at times total spontaneous disappearance of both clot and phlebitis from jugular and sinus, although every rational sign of their former presence had been distinct. It is to be hoped, therefore, that the surgeon will consider well the curative powers of nature, as well as the possibilities and value of his intervention for the removal of purulent foci in sinus or brain. The proportion of cures will doubtless be somewhat reduced by such conservatism, but it will be a less open question, how many of the cases have been operated upon needlessly; for it is not invidious to note that few surgeons have met more than one or two cases demanding operation, while Victor Horsley seems not yet to have employed in a single instance the operation which he is commonly credited with devising.

#### SURGERY OF THE URETERS.

As a result of a clinical, biographical, and experimental research, VAN HOOK (*Journal of the American Medical Association*, vol. xxi., No. 26) announces the following conclusions to an extremely able and scholarly paper:

1. The extra-pelvic portion of the ureter is most readily and safely accessible for exploration and surgical treatment by the retro-peritoneal route.

2. Hence all operations upon the ureters above the crossing of the iliac arteries should be performed retro-peritoneally, except in those cases in which the necessity for the ureteral operation arises during laparotomy.

3. The intra-pelvic portion may be reached by incision through the ventral wall, the bladder, the rectum, the vagina in the female, the perineum in the male, or by Kraske's sacral method.

4. The ureter is not only exceptionally well protected from injury, but by its elasticity and toughness resists violence to a remarkable degree.

5. The histology of the ureters furnishes most favorable conditions for the healing of wounds.

6. Longitudinal wounds of the ureter at any point heal without difficulty in the absence of

septic processes, under the influence of ample drainage.

7. In all injuries where the urine is septic before the operation, or where the wound is infected during the operation, drainage must be effected.

8. The chemic composition and reaction of the urine must be studied in all injuries to the ureter, the urine being rendered acid, if possible, and the specific gravity kept low.

9. The pelvis of the ureter is, *ceteris paribus*, the most favorable site for wounds of the ureter, since scar-contraction is not so likely there to be productive of ill results.

10. In aseptic longitudinal wounds of the ureter occurring in the course of laparotomy, suture may be practised and the peritoneum protected by suture.

11. Transverse wounds of the ureter involving less than one-third of the circumference of the duct, should be treated by free drainage (extra-peritoneal), and not by suture.

12. In transverse injuries in the continuity of the ureter, involving more than one-third of the circumference of the duct, stricture by subsequent scar-contraction should be anticipated by converting the transverse into a longitudinal wound and introducing longitudinal sutures.

13. In complete transverse wounds of the ureter at the pelvis, sutures may be used if the line of union be made as great as possible.

14. In complete transverse injuries of the ureter in continuity, union must not be attempted by suture.

15. In complete transverse injuries of the ureter in continuity, union without subsequent scar-contraction may be obtained by the writer's method of lateral implantation, as described.

16. In complete transverse injuries of the ureter very near the bladder, the duct may be implanted, but with less advantage, into the bladder directly.

17. At the pelvis of the ureter, continuity after complete transverse injury may be restored by Kuester's method of suture, providing the several ends can be approximated by slightly loosening the ureter from its attachments.

18. Rydgier's method of ureteroplasty in such injuries may be tried if other methods cannot be utilized. The primary operation should at least fix the ends of the tube together as nearly as possible.

19. In both transperitoneal and retroperitoneal operations the ureteral ends can be approximated by Van Hook's method even after the loss of about an inch of its substance.

20. The use of tubes of glass and other materials for the production of channels to do duty in place of destroyed ureteral substance must be rarely satisfactory, and even if temporarily successful, the duct is almost sure to be choked by scar-contraction.

21. The implantation of the cut ends of a ureter into an isolated knuckle of bowel is objectionable,—1, because the bowel is not aseptic; 2, because the operation is too dangerous.

22. In injuries of the portion of the ureter within the pelvis, with loss of substance, the ureter should be treated as follows: If possible, the continuity of the ureter should be restored by the writer's method.

23. If this is not possible, the ureter, if injured in vaginal operations, should be sutured to the base of the bladder with a covering of mucous membrane as far forward as possible, with a view to a future implantation or formation of vesico-vaginal fistula with kolpo-kleisis.

24. In injuries to the pelvic ureter during laparotomy, where the continuity cannot be restored, and where temporary vaginal implantation cannot be effected in the female, or vesical implantation in the male, the proximal extremity of the duct should be fastened to the skin at the nearest point to the bladder.

25. In ventral ureteral fistulæ opening near the bladder, the ureteral extremity may in some instances be planted directly into the bladder without opening the peritoneum.

26. In such cases where the ureter will not reach the bladder a flap may be raised from the anterior vesicle wall and reflected upward, extra-peritoneally, to meet the ureter and form a tubular diverticulum.

27. Such a flap may be so elongated by a preliminary operation to transplant the peritoneum back of the fundus, or by accurately suturing it there at a single sitting, that median ventral fistulæ of the ureter may be cured if they open at any point an inch or more below the umbilicus.

28. Symphysotomy is a valuable and justifiable preliminary step in these plastic vesical operations.

29. It is legitimate when both ends of a cut ureter open upon the abdominal wall to try Rydgier's method.

30. Implantation of one or both ureters into the rectum is absolutely unjustifiable under all circumstances, because (1) the primary risk is too great; (2) there is great liability to stenosis of the duct at the point of implantation; (3) suppurative uretero-pyelo-nephritis is al-

most absolutely certain to occur, either immediately or after the lapse of months or years.

31. Ligation of the ureter to cause atrophy of the kidney is unjustifiable.

32. Extirpation of a normal kidney for injury or disease of the ureter is absolutely unjustifiable, except where the ureter cannot be restored in one or other of the ways cited.

#### THE TREATMENT OF INTESTINAL OBSTRUCTION.

In the discussion of this subject at the annual meeting of the British Medical Association, PAGE holds that after careful examination under chloroform and failure to detect the seat of trouble, immediate abdominal section is indicated.

HUTCHINSON stated that, as a result of wide inquiries among his professional friends, he had a strong impression that laparotomy for intestinal obstruction of an unknown origin was very seldom successful, nor was he quite free from the suspicion that the operation in itself presented a cause of danger. He held that it was generally admitted at the present day, with all our improvements, that the fatality from strangulated hernia operations ranged from twenty-five to fifty per cent., we being in this respect not a whit better than our forefathers, no modern surgeon affording the excellent statistics of Mr. Luke; this despite the fact that many cases are operated on which would formerly have been reduced. Hence it would seem that, taken as a whole, the fatality of strangulated hernia has increased. Arguing from this, Hutchinson held that if it should become a common practice in intestinal obstruction to operate early and without attempting to relieve by other means, the fatality in this class of cases would be greatly increased. He himself strongly urged the importance of taxis, and was always accustomed to use all the force that his hands possessed, and often regretted that they tired so soon. Death, after forcible taxis, is extremely rare. Three patients in his practice perished after reduction of femoral hernia, but not one for inguinal. In the last twenty years he has strongly advocated abdominal taxis. This he applied by putting the patient under full anæsthesia and vigorously kneading the abdomen, the intestines being pushed from side to side. The patient is then turned on his belly, and in this position is well shaken; lastly, he is held head downward and again shaken up and down. Enemata are also administered with the body inverted. Many successes followed this manipulation. In some

instances obstruction has lasted for many days. Diagnosis of the precise lesion, excepting in the case of intussusception, is usually an impossibility. Obstruction from gall-stones are cases in point. Operations in these have been repeatedly performed, never with a correct diagnosis beforehand, and often with fatal result; whereas, if left alone, nearly all these cases recover.

HUME agreed with Hutchinson as to the present unsatisfactory result of operation in cases of internal obstruction, but took exception to taxis as increasing the vulnerability of the peritoneum.

COUSINS had two successful cases from following the Hutchinson method of taxis.

MORISON stated that he had seen four cases of hernia reduced *en bloc* with four deaths. He holds that herniotomy is very much less fatal than it was formerly, and that it is distinctly safer than vigorous taxis. In regard to internal intestinal obstruction, he stated that of all cases he had operated upon, when seen post mortem, intussusception excepted, he had never observed one which he could imagine likely to be benefited by such treatment as Mr. Hutchinson suggests. Morison showed that acute typhlitis and perityphlitis sometimes present the symptoms of obstruction, and called attention to the dangers of Hutchinson's manipulations in such cases. In chronic and incomplete cases of obstruction he holds that the best results will be obtained by washing the stomach out, the administration of nutrient enemata, the free use of opium, and stopping of supplies by the mouth. Nearly all acute cases die; certainly not five per cent. recover. He holds, however, that operative treatment will soon demand first consideration.

RIVINGTON called attention to the fact that the heavy mortality of laparotomy for obstruction is due to the fact that the surgeon is called in too late. Hence it is that Hutchinson can truthfully state that at the London Hospital there has not been a recovery from an abdominal section for obstruction, save in a single case of strangulation by a band. When the number of cases of operation within twenty-four hours have been put on record it will be fair to compare the results obtained by abdominal taxis and delay.

NEWMAN, as did nearly all the participants in this discussion, strongly urged the early administration of chloroform and careful examination of the abdomen during the relaxation accompanying this drug, followed by an immediate exploratory incision. He holds that the opening should be small, and if there is failure

to find the seat of obstruction through this opening, the bowel should be short-circuited by Senn's method, or enterostomy should be performed. When the bowel has been emptied of its contents, then the abdomen may be freely opened and the nature of the obstruction discovered and treated according to the individual requirements of the case.

#### RESECTION OF THE RECTUM AFTER THE REMOVAL OF MALIGNANT GROWTHS.

MARCY (*Matthews's Medical Quarterly*, vol. i., No. 1) holds that as soon as the diagnosis of rectal cancer is established, while the invasion of the parts is yet limited and local, inguinal colotomy is to be performed. The operation must be performed in two different stages,—that is, a loop of the descending colon is to be fixed in the abdominal wound, and there allowed to remain for several days, until the peritoneum is shut off by adhesive inflammation, before the intestine is opened. Performed in this way, colotomy is an operation of comparatively little danger. The lower segment of the bowel is thus put at rest, emptied of its contents, and easily disinfected.

This having been accomplished, an incision is made in the median line posteriorly to a point just below the end of the coccyx. The coccyx and a sufficient portion of the sacrum are removed to permit ready access to the bowel. The intestine is first freed posteriorly for about two-thirds of its circumference, and the peritoneal cavity is opened sufficiently to allow of easy manipulation of the intestine. The rectum is now divided transversely at the lower border of the disease; the upper segment is split longitudinally along its posterior wall, thus not only exposing the diseased structures, but facilitating the dissection of the intestine from its anterior attachment, which, in the male, is the more difficult because of the intimate relationship of the parts to the prostate and the base of the bladder. When this dissection is effected, the bowel is divided transversely above that portion which has been invaded by the disease. A further division of the mesorectum is now made sufficient to loosen the attachment of the intestine, so that its upper portion may be readily brought down to the line of its inferior division. This having been accomplished, the continuity of the gut is restored by suturing, or, in the case reported by Marcy, the Murphy button, reinforced with a line of sutures. The peritoneal opening is then sewed, and the wound, according to Marcy, is closed without drainage. The discharge of the

button is insured by a silk suture secured to it and brought out through the anus.

The advantages obtained by the operation are the radical removal of the disease, which, when accomplished at a sufficiently early period, gives expectation of further exemption from it. The sphincter and the anal structures are retained uninjured in character and function. The external tissues are normally approximated, and the lesion of the sacrum gives very little, if any permanent disability.

Subsequent operation for the restoration of the intestine divided in the colotomy, and its replacement in the abdominal cavity, restores the bowel in its continuity and function.

#### APPENDICITIS.

ROBINSON (*Mathews's Medical Quarterly*, vol. i., No. 1) founds the diagnosis of appendicitis upon pain and tenderness in the region of the right iliac fossa, and vomiting, tympanitis, and temperature. The pain is appendicular colic, which may be due to the amount of peritoneal surface damaged by the invasion of the infective matter. The constipation, the tympanitis, and vomiting are reflex. Lameness is due to pressure on the lumbar plexus, and the sudden cessation of pain may denote that the foreign body has been expelled into the cæcum. Oedema may be induced, or hemorrhage, or phlebitis in the right iliac fossa. Robinson compares the appendix to the tonsils, stating that it is subject to similar temporary inflammations at the same ages in both sexes. It is lymphatic in structure. Its glandular element is large.

One-half the appendicitis is catarrhal or parietal, and should not require surgical interference. Relapsing appendicitis is not a dangerous malady. All suppurative and perforative cases of appendicitis should be operated on as soon as diagnosed.

As a reason for the greater frequency of the affection in males than in females, the author suggests that Gerlach's valve is larger in men than in women. Robinson states that he knows of two surgeons who have operated on seventeen cases of diffuse peritonitis following appendicitis, and in every instance with a fatal result. Treves says that eighty per cent. of cases of appendicitis get well spontaneously. Talamon says ninety per cent. get well without operation. Guttman treated medically one hundred cases, and four died.

Robinson finally closes his paper with the statement that observation and practice seem to teach less surgery on the appendix than

formerly. Judgment is becoming more accurate as to what cases demand operation. The findings at autopsies would seem to limit operative work more and more.

#### APHORISMS IN THE TREATMENT OF SYPHILIS.

LANG (*Centralblatt für die Gesamte Therapie*, xii. Jahrgag, 1894), under the above heading, starts with the assertion that mercury and iodides are universally conceded to be anti-syphilitics, and that the only difference of opinion lies in the time and the manner of using these drugs, and the period during which they should be continued. Sarsaparilla, he holds, is also of great value, so much so that many cases treated in vain by the specifics recover in an astonishing manner when this drug is administered. In extremely feeble cases he holds that the best results are often obtained by paying strict attention to diet and hygiene, by administering sarsaparilla, and then finally giving the specifics. He employs a strong decoction, the dose being 2 or 3 teaspoonfuls. The iodide of potassium, he believed, is often given in unnecessarily large doses; in ordinary cases, from 4 to 30 grains a day will answer. When it is necessary to be careful of the stomach the iodides are given by the rectum, 15 to 60 grains being dissolved in 8 to 12 ounces of warm water, milk, or nutrient enema. In one case Lang administered the iodides subcutaneously in the form of a fifty-per-cent. solution, using from 4 to 8 grains a day. The pain incident to this injection may be avoided by incorporating codeine with the iodide in the proportion of 1 to 2 parts to 100.

Mercury acts unfavorably in cases of cancer, tuberculosis, malaria, or degenerative processes in general. The hemorrhagic diathesis is also exaggerated by this drug. Exceptionally even very small doses of mercury produce fatal poisoning. Thus two or three rubbings have produced sloughing and ulceration of the bowel and death. Fournier reports a case treated by him some years ago which showed no especial reaction to mercury, but, returning on account of recurrent brain syphilis, suddenly developed symptoms of poisoning under inunction cure which very nearly resulted fatally. Attention is also called to the chronic form of mercuric intoxication characterized by alteration in the nervous system. Even acute mercuric poisoning can occasion similar alterations. In some cases paralysis developed, in others polyneuritis.

Lang administers pills which should be made up fresh according to the following formula :

R Protiodide of mercury, gr. xxxii;  
Extract of opium, gr. viii;  
Lanoline, gr. xxiv;  
Milk-sugar, gr. lxxii.  
Make 50 pills.

Or, calomel or bichloride of mercury may be used in appropriate doses. Iodide of potassium is given in the same way.

Or,

R Potassium iodide,  $\mathfrak{z}$  iiss;  
Milk-sugar,  $\mathfrak{z}$  ss;  
Lanoline, gr. xlviii.  
Ft. pil. No. 50.

Or,

R Arsenbus acid, gr. iv;  
Milk-sugar,  $\mathfrak{z}$  ss;  
Lanoline, gr. xlviii.  
Ft. pil. No. 100.

Of the iodide pills, 3 to 15 are taken daily.

The inunctions afford an extremely powerful means of influencing syphilis, although they are open to the same objection which obtains against dosage by the mouth,—*i.e.*, the quantity absorbed is never definitely known. It is probable that a certain amount of mercury remains *in loco* for some length of time and is gradually taken up. It is difficult to account on other grounds for stomatitis developing weeks after the cessation of inunction cure. Absorption is equally uncertain in hypodermic injection. Unfortunately, most of the injection masses are so composed that the active principle, being heavy, sinks to the bottom, and, as Ullmann says, often a difference in strength of ninety per cent. occurs between two injections of the same bulk. The author uses a fifty-per-cent. gray oil, of which he injects at one time .05 gramme, and repeats the injections at intervals of three or four days. He selects the subcutaneous tissues of the interscapular region, as in the gluteal region there is danger of striking veins. His first injection is made at the base of the neck, an inch to the left of the middle line; each following injection is made an inch lower down until six are placed, when the skin on the other side of the central line is employed in the same manner. As a first treatment from eight to twelve such injections are required. Recurrences require from four to eight. Exceptionally, more than twelve injections may be needed. In this case the tissues are selected further to one side of the line of the vertebræ. This is the treatment preferred by Lang.

#### OPERATIVE TREATMENT OF VARICOCELE.

KOEHLER (*Berlin Klin. Woch.*, No. 50, xxx. Jahr.) holds that when a patient with well-developed varicocele complains of pain which is not relieved by a well-fitting suspensory, when the enlargement of the veins is increasing, or when it is occasioning atrophy of the testicle and reflexly producing a condition of mental depression, operation is imperatively required. The method of choice consists in exposing the veins by free incision, isolating them, and tying each one separately high up and low down, the portion between these ligatures being excised. This excision should be combined with an operation having for its end shortening of the scrotum. This end is easiest attained by tying together the ligated vein ends above and below; then the vertical skin wound is stretched laterally so that it becomes transverse, and the wound is sewed in this position.

#### EXPERIMENTAL RESEARCH CONCERNING TETANUS IMMUNITY.

TIZZONI and CATTANI (*Berlin Klin. Woch.*, No. 51, xxx. Jahr.), on the basis of extended experimental study, state that rats and guinea-pigs, as representing animals exceptionally sensitive to the action of the tetanus bacillus, are no longer susceptible to the injurious effects of this micro-organism when injected with serum of high immunizing power. These serum injections are most efficient when they are administered immediately on the first appearance of symptoms of tetanus. Their effects are much less satisfactory, and are accomplished much more slowly when the local tetanic symptoms have reached their maximum and both local and general manifestations are present. The injections are quite without power when the infection has become general and death is near at hand.

The quantity of serum necessary to cure an animal already exhibiting tetanic symptoms is very much greater than that required to produce immunity. Thus, at least two thousand times the dose necessary for immunity is required to cure the developing disease, and correspondingly, when the symptoms of tetanus are well advanced, the dose must be still further increased, so that a quantity of the antitoxine one hundred and fifty times greater than that required at the beginning of tetanus is necessary in these cases.

The injection of the serum does not immediately affect the symptoms already developed; indeed, after a time, it slightly accentuates

them; but it has the effect of localizing them and of protecting the system at large from general infection. The symptoms, having been in the first place localized, subside very slowly, cure requiring several weeks.

Even though a dose considerably more powerful than that required to accomplish cure is given, it does not essentially hasten convalescence. The immunizing and curative power of the serum depends solely upon the amount of antitoxine it contains, and not upon the varying strength of this antitoxine. Hence it follows that satisfactory results can be obtained from serum of different potency provided the experimenter knows exactly what this potency is, and can gauge his volume dose accordingly. By precipitation with alcohol the serum loses none of its strength. Hence this precipitate can be used as effectively as can the serum. The serum of various animals, the horse and the dog for instance, is potent against tetanus, the essential point being to discover in each case the amount of antitoxin contained in a given volume. With serum of the highest immunizing power,—1 to 1,000,000,—if the results of experiments on animals can be utilized as a basis for the treatment of the human, about .7 cubic centimetre would be required for the cure of a man suffering from the first symptoms of moderately acute tetanus. If the disease is further advanced, 21 cubic centimetres will be required. If the alcoholic precipitate is employed, 5 to 6 centigrammes should be used in the first case, 10 to 12 grammes in the second.

#### TREATMENT OF CORYZA.

In the *Tribune Médicale* (27 année, 2e sér., No. 2) the following directions are given for the treatment of acute coryza: (1) Confinement to the room; (2) washing of the nose, three times daily, either by snuffing up the medicament, or by irrigation with infusion of eucalyptus leaves, or simply a glass of water as hot as can be borne, to which is added a soup-spoonful of carbolic lotion, 1 to 20; (3) every two hours, after having blown the nose, a pinch of the following prescription:

R Chlorhydrate of cocaine, .10  
Menthol, .20  
Salicylic acid, .50  
Boric acid, 4.  
Powder of marshmallow, 10.  
Make into fine powder.

(4) if the frontal pain is extremely severe, take three or four times a day a pill made up according to the following prescription:

R Crystallized nitrate of aconitine, gr.  $\frac{1}{16}$ ;  
Bromhydrate of quinine, gr. xvi;  
Licorice powder.  
Make ten pills.

(5) when there is irritation of the skin, smear the nasal orifice and the upper lip with

R Vaseline, 10 parts;  
Boric acid, 1 part.

#### THE IMPENDING REVOLUTION IN MILITARY SURGERY CAUSED BY THE NEW INFANTRY RIFLE.

ANDREWS (*Journal of the American Medical Association*, vol. xxi., No. 26), after considering the changes which will be necessary in the position of surgeons and assistants at the time of battle,—changes necessitated by modern weapons,—contrasts the wounds produced by these weapons, particularly the rifle of small calibre, using smokeless powders, and injuries from the Springfield rifle used during the Civil War. He states, in a general way, that the old gun tears and shatters, the new one pierces; that the old projectile creates more shock and stops a wounded man more effectually; the new one causes less shock and less injury. It is evident that in future fighting most of the wounds will occur at the perforating and not at the shattering distance,—that is, between 350 and 1800 yards; hence field-surgery will have to deal with new conditions.

1. The wounds being smaller and less shattering, shock will be less, and the missiles will generally go through the body, and not require to be extracted.

2. The bullet, being so small, will have much less tendency to carry in with it patches of septic clothing and skin, and any bits that are lodged in the track of the wound will be so minute that a deep flushing of the wound with antiseptics will often sterilize the injury.

3. In cases where there is actually some chipping of a joint surface it will be possible to open the joint on the field, pick out the fragments, sterilize the cavity, and close it up, thus avoiding amputation.

4. It will in future be possible to avoid a large portion of the amputations and excisions which were formerly necessary.

5. In perforating wounds of the abdomen the tearing of the hollow viscera will be much diminished, giving a hopeful opportunity to save life by laparotomy on the field.

6. As prompt antisepticism of the wounds will be important, the hospital corps will have to be instructed how to do it before they bring in the patient.

7. The dispersion of the wounded over wide areas will increase the difficulty of prompt "first aid."

8. Field-surgery will be more scientific, and require a greater variety of operations; hence the poverty-stricken little cluster of instruments formerly furnished by the government to field-surgeons must have additions adapted to the new exigencies of the battle-field.

**OPHTHALMIC NURSING.** By Sydney Stephenson, M.B., F.R.C.S. (Edin.). With sixty-one illustrations. London: The Scientific Press, Limited, 1894.

Dr. Stephenson informs us that his volume is the outcome of instruction given to nurses at the Ophthalmic School at Hanwell, and certainly those who have had the pleasure of listening to these lectures are to be congratulated upon the excellent instruction which they have received. It was high time that a book devoted especially to the nursing of diseases of the eye should be prepared, inasmuch as other branches of medicine have not been neglected in this respect. This one is thorough, practical, and sufficiently illustrated, although some of the plates, for example, the frontispiece, and the one illustrating the rods and cones, are fearfully and wonderfully made. This book may with propriety be read not only by nurses, but by physicians who are interested in the subject of ophthalmic operations, and we heartily commend it.

**TEXT-BOOK OF NORMAL HISTOLOGY, INCLUDING AN ACCOUNT OF THE DEVELOPMENT OF THE TISSUES AND OF THE ORGANS.** By George A. Piersol, M.D. With four hundred and nine illustrations, of which three hundred and fifty-eight are from original drawings by the author.

Philadelphia: J. B. Lippincott Company, 1893.

From the opening chapter, on "The Cell and the Tissues," to the appendix, containing a description of the most useful histological methods, this work is clear in expression, accurate in description, beautiful in illustration. Dr. Piersol's well-known skill as an artist has served him in good stead, and of the numerous plates scattered through its pages, a few of which are taken from well-known

authors, more than one hundred and fifty are the work of his own clever pencil. Not only the original drawings, but those which have been selected, exactly meet the needs of the student in his efforts to learn and retain the facts of microscopical anatomy. As Dr. Piersol himself points out, they are sufficiently diagrammatic to be efficient aids in the comprehension of the text, but are none the less faithful likenesses of the original preparations. Among the many commendable features, there is one to which we would particularly call attention,—namely, that the preparations from which the drawings have been made, as far as possible, have been taken from human tissues.

In a book that is symmetrical, it is difficult to select, even if it were advisable, chapters that are particularly noteworthy; but, perhaps, owing to Dr. Piersol's early training as an ophthalmic surgeon, it is not unnatural that the section devoted to the eye and its appendages is singularly good, not only in its descriptions, but in the accuracy and beauty of its illustrations. For example, the plates illustrating a section through the ciliary region of the human eye, the human choroid, and the anterior segment of the human eye, including cornea, sclera, iris, ciliary body, and lens, have no superiors anywhere, and we doubt if they have their equals. This book at once takes front rank, and should be in the possession of every one who is interested in this important subject.

The publishers are to be congratulated upon the excellence of the book-making, the clear type, the satisfactory paragraphing, and the emphasizing by the use of heavy type of the important words in each section. A satisfactory index completes this capital textbook.

**ESSENTIALS OF PRACTICE OF MEDICINE ARRANGED IN THE FORM OF QUESTIONS AND ANSWERS.** By Henry Morris, M.D., with an appendix on the Urine, by Lawrence Wolff, M.D., and a formulary by W. M. Powell, M.D.

Philadelphia: W. B. Saunders, 1894.

The author tells us in his preface to the third edition that the book has proved of value to the medical student to such an extent that at the end of three years a third edition is called for. This fact seems to prove that it does fulfil the office for which its publisher and the author intended it, and that it contains a careful summary of most of the facts in connection with the study, if not of the application, of practical medicine. The statement, however, that the very latest treatment has been inserted is hardly accurate. For example, under

"Typhoid Fever" we are unable to find anything about the use of the Brand or cold-bath treatment. Under "Diphtheria" nothing is said of the employment of peroxide of hydrogen locally, and the dose of corrosive sublimate, which is recommended, has been criticised as excessive,—namely,  $\frac{1}{10}$  of a grain every two hours. Other therapeutic points are discussed in a similar manner. In regard to etiology, nothing is said under "Erysipelas" of the fact that the disease is due to micro-organisms, but we are told that it is "due to a special poison, and is slightly contagious."

OUTLINES OF PHYSICAL DIAGNOSIS OF THE THORAX.

By A. M. Corwin, A.M., M.D.

Chicago: W. T. Keener Co., 1893.

This is a little book bound in a pliable cover, small octavo, containing one hundred and twelve pages, and is intended as a tree upon which the student may hang the ideas which he learns in the study of physical diagnosis. We have no doubt that to those students who follow Dr. Corwin's course it will be a useful guide and aid.

CLIMATES OF THE UNITED STATES IN COLORS. By

Charles Dennison, A.M., M.D.

Chicago: W. T. Keener Co., 1893.

This small book is composed of a large number of maps showing the direction of the wind, the humidity, temperature, cloudiness, and rainfall of the entire United States, with the object of providing the physician and others with a reliable guide in the selection of a climate, or in the prognostication of storms. The fact that so careful a worker as Dr. Dennison has prepared these maps is a sufficient guarantee of their accuracy, and the popularity of them in previous editions has shown that this unusual way of providing medical information has proved popular.

Any one who is called upon to determine upon the climate to which a patient should go should be possessed of this volume.

THE TECHNIQUE OF POST-MORTEM EXAMINATION. By

Ludwig Hektoen, M.D. Illustrated.

Chicago: W. T. Keener Co., 1894.

In this small octavo of one hundred and seventy pages, Dr. Hektoen has given the student a very valuable manual, which will be of use to him for reference, should he be wise enough to make as many post-mortems as possible after the diploma has been conferred. The method of opening the various cavities of the body and of examining the organs macroscopically, together with the incisions which should be made for the expo-

sure of important parts of these organs, are all clearly detailed, and it is evident that the illustrations have been taken from the post-mortem table direct, and are not merely theoretical diagrams. It is always a pleasure to review a book which is of value, and a still greater one when the reviewer is thus given an opportunity of praising the writings of one who has contributed so much interesting and valuable material to the study of pathology in America.

A PRACTICAL TREATISE ON DISEASES OF THE SKIN FOR THE USE OF STUDENTS AND PRACTITIONERS. By James Nevins Hyde, A.M., M.D.

Philadelphia: Lea Brothers & Co., 1893.

America is as fortunate in the number of its eminent dermatologists as is Germany. The text-books which have been written by Duh-ring, Taylor, and Hyde have done more than anything else towards rendering the study of this subject attractive and profitable. The third edition of Dr. Hyde's book possesses all the advantages which the previous editions have contained, and is certainly one of the most practical works for the ordinary physician who is forced to treat diseases of the skin. In the beginning of the description of each disease is the derivation of its ordinary name, its synonyms, and the frequency with which it occurs. A peculiar advantage of the book is, it seems to us, the clear descriptions of the treatment which is to be instituted. In many instances standard prescriptions are given, while in other cases suggestions as to the combinations of remedies are so practical that the physician has no difficulty in applying the remedy needed in an individual case. The illustrations for a book of its kind are unusually copious, and in many instances are taken from the writer's own practice and not copied from other authors, as is so often the case. References are given with sufficient frequency to enable the special student of dermatology to carry on his researches in dermatological literature as far as he desires, yet are not so frequent as to spoil the appearance of the pages, or to injure the continuity of the text.

It is not surprising that Dr. Hyde's book has reached its third edition in ten years, for, although it deals entirely with a specialty, it is just the work for both the specialist and the general practitioner. A valuable portion of the book is the recognition by the author of the most recent bacteriological researches in connection with skin-disease, as, for example, the recognition of the streptococcus pyogenes as the streptococcus of erysipelas.

### LOCAL TREATMENT IN DIPHTHERIA.

READ BEFORE THE NEW YORK STATE MEDICAL SOCIETY,  
FEBRUARY 7, 1894.

BY A. JACOBI, M.D.,

Clinical Professor of Diseases of Children, Medical Department,  
Columbia College, New York.

THE bacilli and the toxine of diphtheria will invade the circulation by direct inhalation into the lungs in but very few instances. These are some of the cases in which the constitutional symptoms precede the local. Local deposits, however, are not always visible, as, for instance, in those cases in which

the constitutional symptoms are connected with diphtheria of the nose, where but few deposits take place, and the virus—the nasal discharge being slightly bloody—is absorbed directly into the open blood-vessels. In the vast majority of cases, however, local deposits are easily found, and mostly on the mucous membranes, rarely on that of the intestines, very exceptionally the gastric, more frequently the genito-urinary, particularly the vagina, rarely the bladder, in most cases the pharyngeal or respiratory mucous membranes. Besides, diphtheritic pseudo-membranes are found on abrasions of the skin by scratching, eczema, erysipelas, vesicatories, and in surgical wounds, such as circumcision and amputation wounds,

tracheal incisions, resection of tonsils or removals of adenoid growths. It is on the external wounds that the effect of local treatment can be best studied.

The local remedies employed have been used for the purpose of either directly destroying the pseudo-membrane, such as nitrate of silver, carbolic acid, the actual cautery; or to dissolve them, such as the alkaline carbonates, the chlorides, steam, papayotin; or to act as astringents, such as lime-water and the chloride and subsulphate of iron; or to disinfect, such as the potassic chloride, chloral hydrate, turpentine, carbolic acid, mercury, sulphur, bromine, iodide, iodoform, chlorine-water, and peroxide of hydrogen. The methods of application have been either direct local administration by the attendant, or washes and gargles, sprays, injections, inhalations.

The local treatment of the mouth and throat has two indications,—first, to keep the mucous membrane of the cavities in a healthy condition or restore them; second, to influence the diseased surface. Gargles in any shape will reach the oral cavity only. They never touch anything beyond the anterior pillars of the soft palate, and seldom more than a small part of the tonsil. The gargles with chlorate of potassium, the benzoate or biborate of sodium, have only a preventive, not a curative, effect; still, they ought not to be neglected when the children are old enough to use them. Mild solutions of the above salts may also be introduced into the mouth of babies from time to time by means of a brush or a pipette. Local applications to the throat, even where they are possible, ought not to be made with powders. They are apt to nauseate and produce vomiting by their mere contact. Even powders for internal administration require careful mixing with water, or they are liable to irritate the throat; thus, the direct application of calomel, the oxide of mercury, or sulphur ought to be avoided. Applications of substances with bad taste or those that give pain must be avoided, because the struggling and consecutive exhaustion of the patient will do more harm than the remedy will do good. That is so with a number of substances, particularly with the chloral hydrate and even with the chloride of sodium, which was recommended some years ago as a local application to the pseudo-membrane of the tonsil.

In diphtheria the danger arises, first, from suffocation. That can be easily recognized, and the indications for the treatment by mechanical means—that is, intubation or tracheotomy—are readily found. These are the cases

in which repeated fumigations with 10 to 15 grains of calomel, under a tent or in a small room, are used to advantage. Steam will also answer well under the same circumstances. The second great danger is from exhaustion and heart-failure, which is not merely functional, but organic. It is always to be feared, for it is known that apparently mild cases may thus perish. The indication, then, is to save as much nerve strength as circumstances will permit. The third great danger is sepsis, which is not to be feared to an equal degree in all cases, for those cases of diphtheria which are confined to the tonsils, with its large amount of elastic tissues surrounding it, and with their scanty communication with the lymph system, are not liable to produce sepsis, and thereby to terminate fatally. Both sepsis and fatal termination are the results rather of those cases which are confined to or implicate the nares and the naso-pharynx.

Where the diphtheritic pseudo-membrane is within reach, it ought to be either destroyed or disinfected. For that purpose a fifty-per-cent. solution of carbolic acid in glycerin may be applied several times a day, or the tincture of iodine, or solution of 1 part of the bichloride of mercury in 100 or 500 parts of water. It is in these cases that chlorine-water has been injected through the surface into the upper layers of the tonsils. But we must never forget, first, that only a small part of the pharynx is accessible to such treatment, and that it is only one class of patients who can be subjected to it. In order to be effective, the application must be thorough. None but adults or large children, and of them only a small number, will submit to opening their mouth and having the applications made. It is that very class of patients who can be induced to gargle with anything like success. Smaller children will object, will defend themselves, will struggle. It takes many a good minute to force open the mouth; meanwhile, the patient is in excitement, perspiring and screaming, exhausting its strength. You may succeed in forcing open the jaws; then there begins the practice of making applications, of swabbing, of scratching off the pseudo-membrane, of cauterizing, of burning. The struggling child will prevent you from limiting your application to the diseased surface. You cannot help injuring the neighboring epithelium; thus the process will spread. Instead of doing good, you have done harm; for, indeed, no local application can do as much good as the struggling of the frightened child does harm. I have seen them die while defending themselves

against the attempted violence, leaving doctor and nurse victorious on the battle-field. It is incredible, but it is true, that more than one has recommended using the electro-cautery or the thermo-cautery on the throat of the baby, after forcing the mouth open. It is almost incredible, for you are aware that the offenders cannot have been ignorant of the fact that what they can reach with their instruments is but very little besides the tonsil, and they might have known that the tonsils are not apt to favor the inception of sepsis into the system.

There is an easy way of using disinfectants on the throat and mouth: give medicines which are, at the same time, disinfectants, digestible, and easy to take; give them in small doses; give them frequently; see that when they have been given, no water nor milk is taken immediately afterwards, so as not to wash them off from the mouth and throat. Such medicines are mild dilutions of the tincture of chloride of iron, or lime-water, or boric acid, or bichloride of mercury, most of which will act both by their constitutional and their local effect.

Diphtheria is most dangerous when located in the nose and naso-pharynx. The changes taking place in the nares may be an extensive catarrh, besides the diphtheritic deposits. The diphtheritic membranes are sometimes very thick, and contain a great deal of fibrin. Sometimes they are so thick as to clog the nares and prevent respiration. Underneath them copious absorption of toxins may take place. In most cases, though, the diphtheritic membranes are not so thick. Some of them macerate very readily, and the toxin is very speedily absorbed through the exceedingly copious lymph-ducts, and sepsis is the result. In some cases of diphtheria the membranes can hardly be seen. The discharge from the nose is liquid and acrid, contains small flakes and some blood. These are the cases in which the toxin is absorbed directly into the blood. All of these forms may lead to necrosis and gangrene of the tissue, and produce a very peculiar sweetish, nasty odor. Thus, the inhaled air is poisoned, and, being carried down into the lungs, acts as an additional danger. The most dangerous locality is the posterior nares, with their direct communication with the lymph-bodies below the angle of the lower jaw. The pseudo-membranes, the lymph-ducts, lymph-bodies, swarm with bacilli and toxin, with streptococci, with staphylococci, and lead to immense tumefaction between the ears and clavicles, to the formation of multiple abscesses, to hemorrhages, to sepsis. All of these forms of

nasal diphtheria require immediate, persistent, and efficient local treatment, for it is safe to say that every case of nasal diphtheria has a tendency to terminate fatally. The local treatment is to consist in cleansing and disinfecting. In most cases these two are identical, for if we simply succeed in washing out the macerating material, that would prove sufficient. In order, however, to have that effect, the washing and disinfecting must be done often,—every half-hour, every hour, every two hours. In the bad cases, in which the nares are clogged with pseudo-membrane, the cleansing and disinfecting is to be preceded by forcing a passage through the nares with a probe covered with wadding and dipped in carbolic acid. Particularly is this indication urgent when there is sopor, which owes its origin partly to the difficulty of respiration and partly to the septic condition. The methods of local treatment, besides the one just described, are the application of ointments into the nose by means of the brush or wadded probe, or the use of the spray or syringe or irrigator, or the use of a spoon or feeding-cup, through which liquids are poured into the nares.

In making local applications it is important that the whole surface should be touched; therefore ointments are not available in the average cases where the whole naso-pharynx is the seat of the affection. The atomizer will seldom convey a sufficient amount of liquid into the cavities to be of much use. A spoon or small feeding-cup, the nozzle of which is narrow enough to enter the nose, will do fairly well, and will allow the introduction of liquids into the nares in small or large amounts, all of which will enter the throat, be either swallowed or flow out. The irrigator is liable, by undue pressure, which cannot always be well measured, to injure the ear. It is true that this cannot take place very readily so long as the whole naso-pharynx is covered with pseudo-membrane, but this will not always remain, and then there is a possibility of the injection entering the middle ear. This will take place the more readily the younger the infant, because the pharyngeal orifice of the Eustachian tube is relatively larger and more funnel-like in the very young than in advanced age. I prefer a small glass syringe with a conical nozzle of soft rubber. It will close up the nostril, the pressure can always be well measured and modified, and it is effective. The injections must be made in the recumbent or semi-recumbent position. On no condition must a child be taken out of bed for the purpose of having the nares washed and disinfected. I know of many

cases in which the patient has died simply from being taken up repeatedly.

The applications to be made may be quite simple. In many cases a solution of table salt in water (7 to 1000), or boracic acid (3 or 4 to 500), or lime-water will answer all purposes. The latter is particularly indicated when there is a thin, acrid, slightly fetid discharge. A more efficacious disinfectant than all of those mentioned is the bichloride of mercury, 1 part mixed with 100 parts of chloride of sodium in from 2000 to 10,000 parts of water. It can be used freely.

If moderate quantities of a mild solution of bichloride of mercury be swallowed while being injected, no harm is done. Where there is a fetid odor, the nares ought to be deodorized by carbolic acid or creolin.

Carbolic acid may be used in solutions of from 1 to 10 in 1000 parts of water, but it must not be forgotten that there is some danger in swallowing the carbolic acid, because of the nephritis which it may give rise to. For the same purpose of deodorizing, creolin may be used in one-per-cent. solutions.

For the purpose of dissolving membranes, papayotin (not the proprietary medicine sold under a similar name) has been used in five-per-cent. solutions, either as a spray or injection, or direct applications by means of a sponge or brush. I have used it to dissolve the diphtheritic membranes of the trachea below the tracheotomy tube in greater concentration. Its application in powder does not answer well. For the same purpose trypsin in five-per-cent. solutions has been employed, mixed with bicarbonate of sodium.

The cervical lymphadenitis, of which I have spoken as the result of nasal diphtheria, must be treated persistently and effectively. This treatment may be preventive and curative. The preventive treatment consists in the nasal injections described. When large tumefaction has taken place, tincture of iodine has been applied externally; it is useless. Mercurial ointments have been applied; they are useless, both as a remedy and as a means of massage. Ice externally is rational, but it is useless as long as the infection is not stopped. I have in a number of instances injected iodoform, in ether, into the swelled mass. It is too painful and too inefficacious, and does not pay for the agitation, anguish, and exhaustion of the unhappy baby. So, indeed, there is no remedy, besides the preventive measures, except in long and deep incisions into the immense mass. Do not wait for fluctuations or even semi-fluctuations to become apparent. A great

deal of the swelling is inside the fascia. Abscesses, when they form, are seldom large. The contents consist more of necrotic tissue, which ought to be laid open as soon as possible and disinfected. The incision must be a long one: in most cases from ear to clavicle. The disinfection of the wound may be obtained by subnitrate of bismuth, by tincture of iodine and iodoform, or other antiseptic gauze. No carbolic acid can be used for disinfection, because of its tendency to give rise to hemorrhages. When hemorrhage takes place, it is apt to stop, under pressure with antiseptic gauze; but sometimes, large blood-vessels having been eroded, the hemorrhages are very copious. In such cases the actual cautery, acupressure, sometimes the ligature of blood-vessels, have to be resorted to. Chloride of iron and subsulphate of iron must never be used on such necrotic surfaces. They give rise to a thick coagulated scab, under which septic absorption is apt to take place.

The treatment of diphtheritic paralysis is in part local. Friction and massage of the paralyzed limbs, either dry or with oiled hands, or with alcohol and water, will restore circulation and nutrition to the muscles. The principal indications for local treatment, however, are found in those cases in which the respiratory muscles are paralyzed and life is in imminent peril. Fortunately, these cases are rare, but they require immediate treatment. In the neighborhood of the paralyzed muscles strychnine injections can be made at brief intervals, and the electrical current must be passed so as to stimulate the paralyzed muscles. Care must always be taken, however, not to over-stimulate, thereby paralyzing the muscles, which is the invariable result if the current is allowed to pass through the tissues uninterruptedly.

---

#### THE TREATMENT OF MITRAL STENOSIS.

BY JAMES BARR, M.D.,

Physician to the Northern Hospital, Liverpool, England.

I HAVE entered very fully into the treatment of this affection in my papers in the *Liverpool Medico-Chirurgical Journal* of 1886 and 1887, but must now further elucidate this important subject. I may premise that there are few chronic diseases so amenable to treatment and so compatible with a comparatively long life of comfort if judiciously handled.

In the early stages of mitral stenosis, when the contraction of the mitral orifice is not great, a slight hypertrophy of the left auricle

and right ventricle may be sufficient to maintain the cardiac balance. We should, then, lessen the high arterial tension which is usually present, so as to obviate all strain on the mitral valve, and thus prevent the development of the stenosis. The tension is best lessened by the administration of salines and alkalies, moderate exercise, a light diet, with little fluid. In these cases there is generally a rheumatic tendency, and the mode of life should be prophylactic, against the development of acute attacks of rheumatism. The patient should be warmly clothed with flannel next the skin, and he should avoid all vicissitudes of climate. When at any time the feet are damp or the body wet and chilled, the clothing should be changed and the surface circulation re-established as quickly as possible. The action of the skin should be maintained, and for this purpose daily ablutions are necessary. A morning bath, at a temperature from 60° to 80° F., according to the susceptibility of the patient, with coarse friction afterwards, will be found very advantageous. The combustion within the system should be as thorough as possible, and with this end in view the patient should avoid all close, heated atmospheres, and live as much as possible in the open air. A warm, dry climate is the best. He should live at not too great an elevation from the sea-level, so as to obviate the effects of a rarefied atmosphere, which leads to pulmonary congestion, and further tasks an already overworked right ventricle. The life should be at a low level, not merely so far as the earth's surface is concerned, but in every other respect, and free from all mental worry and care. The patient should be enjoined to "pursue the even tenor of his way" in a happy and contented frame of mind, and simple pleasurable emotions should not be forbidden. Marriage cannot be recommended; and especially in the case of a female, a timely counsel against wedlock and its usual results will be advisable. When the disease is advanced, even strong emotional excitement, irrespective of childbearing, is highly injurious. Some years ago I tried to dissuade a young lady from matrimony, but to no purpose. About twelve months afterwards, under a little over-exertion and domestic anxiety, her heart gave way, and I was called down to Wales to see her dying from cardiac failure and hæmatemesis. However, I have known many non-emotional women, suffering from mitral stenosis, to bear large families. Pregnancy and parturition largely increase a woman's risks under these conditions, but still she can usually be carried safely through

her troubles. A few years ago I saw, with my friend, Dr. G. G. Stopford-Taylor, a woman in the last days of gestation, who was apparently dying from mitral stenosis, with cardiac failure. We discussed the propriety of inducing premature labor, but determined to try the effect of treatment first. She received immediately a hypodermic injection of  $\frac{1}{2}$  grain of atropine, followed by a dose every three hours of 1 minim of liquor atropinæ sulph. and 1 minim of a one-per-cent. solution of nitro-glycerin. She got 5 grains of calomel, and all fluid was absolutely interdicted. In a few hours she was comparatively comfortable, except for the effects of the atropine, and two days afterwards was safely delivered. She made a good recovery.

Some years ago I saw, with Dr. Bowen, a patient affected with mitral stenosis, who, after her confinement, had a large thrombus carried from the uterine sinus and lodged in the pulmonary artery. She was suffering from urgent cardiac dyspnoea, livid, cold, bathed in perspiration, and almost pulseless. Under the influence of 5 minims of liquor ammoniæ fort. every half-hour the clot gradually disappeared, and she made a good recovery. The case was published in the *Liverpool Medico-Chirurgical Journal* by Dr. Bowen. In all cases of blood-clotting there is no remedy equal to strong solution of ammonia, which was first recommended in such cases by Sir B. W. Richardson.

Short of actual fatigue, a fair amount of exercise, even to the extent of climbing hills, will prove highly beneficial, by favoring the circulation, increasing the combustion, and improving the general nutrition. The skeletal muscles contain about a fourth of the whole blood of the body, and this exercise greatly increases the circulation through them, and so increases the capillary area. On the other hand, if they be not used, they require very little nutrition; comparatively little blood passes through them, as it tends to flow in the direction of least resistance; thus the capillary area is diminished and the general arterial tension increased.

The food should be light and nutritious, with a fair proportion of vegetables, and no meal should be so heavy as to unduly distend the stomach. The food should merely be sufficient in quantity and quality to maintain healthy nutrition. I am in the habit of advising my patients to drink as little fluid as possible, never more than two pints a day; and if the tissues be at all flabby, or there be any venous turgescence, I frequently reduce them to half this amount. All fluids drunk have to pass through the circulation before

they are excreted, and any extensive amount only handicaps the right side of the heart without producing any benefit. I know that some physicians like to drench their patients, with the view of washing away effete products, but it is a much wiser plan not to produce more effete products than can be excreted without flushing. The regular use of all alcoholic drinks should be strictly interdicted. Tea, coffee, and cocoa may be left to the discretion of the patient, except so far as quantity of fluid is concerned. With some practitioners milk is a universal food for all the ills to which flesh is heir, but I do not recommend it for rheumatic or gouty patients, and in cases of mitral stenosis it has the further disadvantage of being a liquid food. Tobacco should be forbidden. In this early stage of the disease drugs are unnecessary, except for some complication which may arise, or some failure in compensation from excessive strain or other cause. There is usually not much anæmia, so that iron is not often required, but when prescribed it should be combined with a laxative, and preferably with one which acts on the liver. I have shown that mitral stenosis not infrequently arises in anæmic conditions, and so that cause or associated condition of the lesion should be removed.

If the rules which I have laid down be strictly adhered to, the disease may make slow progress and the patient enjoy many years of a very comfortable life; but the lesion has a progressive tendency, and as the mitral orifice becomes smaller, disturbances in the circulation are more easily developed and the secondary effects become more permanent. The further treatment of the case, beyond the general plan which I have already indicated, will mainly depend on the nature of the complications which arise.

When any indication of failure of compensation in the right side of the heart occurs, there must be no fashionable treatment by graduated exercise on a mountain-side, but the excellent old-fashioned restorative of rest in bed must be at once adopted. If the disease be in an early stage, a few days' rest, a dry diet, and a cholagogue cathartic may be all that are required to restore the *status quo ante*. If a long stay in bed be deemed advisable, then *massage* should be substituted for the loss of active muscular exercise. This improves the circulation in the muscles, increases the quantity of blood in the systemic vessels and so indirectly lessens the pulmonary engorgement and hastens the return venous current.

There is more or less constantly high tension

in the pulmonary circuit, and in my article on the "Etiology of Aneurism" (*Liverpool Medico-Chirurgical Journal*, July, 1881) I have shown how this leads to atheroma; in fact, the only marked atheroma which I have observed in the pulmonary veins has been in cases of mitral stenosis. This pulmonary engorgement dilates the left auricle, causes bronchial secretion, and eventually leads to brown induration of the lungs, with more or less destruction of lung-tissue. These conditions are best obviated by reducing the fluid in circulation, and keeping as much of that as possible in the systemic vessels by the methods which I have already indicated. The lungs may become so engorged that nature seeks relief by a profuse hæmoptysis, and in these cases this is the most direct and best method of bloodletting. Instead of appreciating the efforts of nature, it is no uncommon thing to see the physician attempt to stop the hæmoptysis at all hazards. The patient is plied with gallic acid, ergot, or acetate of lead, which leads to arterial contraction, with still further engorgement of the lungs, and perhaps a fatal issue, if nature does not assert her right by a still more copious bloodletting. In these cases some propose to relieve the right side of the heart by free venesection of the veins of the arm, but they fail to see that you cannot siphon the blood backward, but you only withdraw it in the course of the circulation from the arterial system, which already contains too little. If you wish to bloodlet, you can only do so with any degree of efficacy from the hemorrhoidal veins, which are in immediate communication with the inferior vena cava. In a very urgent case it might perhaps be permissible to perform the operation suggested by Dr. Westbrook, of aspirating the right ventricle. Such cases, however, are best treated by brisk catharsis with saline purgatives; sweet spirits of nitre, or small doses of nitro-glycerin, to increase the capacity of the systemic arterioles and capillaries, and thus indirectly relieve the engorgement of the lungs, lessening the quantity of liquids ingested, so as to diminish as far as possible the fluid in circulation, and then employ such a hæmostatic as turpentine, which clears out the blood lodged in the air-vesicles. I now wish to add another mode of bloodletting by aspirating the liver. Those who have seen cases of death from asphyxia know what an enormous quantity of blood that organ is capable of containing, and how greatly and rapidly it may thus become enlarged. That an analogous condition exists in cases of mitral stenosis is well known, though this chronic congestion may and does lead to a

form of cirrhosis, in which cases the blood will not be so readily abstracted. Therefore depletion of the liver is easily practised in proportion to its size. When there is hæmoptysis, there may be failure in the compensation of the right ventricle, but its force remains fairly good, because when its contractile power is greatly diminished, or there is free regurgitation through the tricuspid orifice, the intrapulmonary pressure at once fails; therefore hæmoptysis affords an indication for relieving the pulmonary engorgement rather than the right ventricle. This, no doubt, could be readily done by bleeding from the arm or jugular, or even more directly by opening an artery, if there were free communication through the mitral orifice, which would enable the left ventricle to withdraw the blood from the lungs as quickly as it pumped it out at the open vein or artery; but there is not; hence we must content ourselves with the rational lines of treatment which I have indicated. With the diminution of the quantity of blood in the lungs, the distention of the left auricle is lessened, and so its contractile power is better able to assist in carrying on the circulation.

In mitral stenosis, so long as the force of the right ventricle remains effective and there is no bronchitis, the blood passing through the lungs is well oxygenated, the left ventricle drives its bright-red blood well into the systemic capillaries; hence patients usually present a florid, healthy appearance, and have not that livid, dusky hue which is so common in cases of mitral regurgitation. Once there is marked failure of the right ventricle, the blood does not pass freely through the lungs, and the left ventricle does not receive a sufficient quantity of oxygenated blood to maintain the systemic capillary circulation. The blood accumulates in the lungs and left auricle, the right ventricle becomes greatly dilated, the tricuspid orifice incompetent, the right auricle distended, the greater part of the blood accumulates in the venous system, so that the veins, down to the minutest radicles, become overloaded; the work of the left ventricle is increased, which now, perhaps, through failing nutrition, gets also dilated; the circulation becomes stagnant, the mucous membrane livid, the countenance bloated and dusky, the surface cold and even death-like. There is usually very little anasarca, because there is no extra blood or excessive pressure in the systemic capillaries. The whole venous system, including the liver and portal circulation, is engorged, and when there is free tricuspid regurgitation

the dropsy not infrequently begins as an ascites. Here you have got not only the overloading of the whole venous system, which necessarily begins in the most distal veins, due to the mitral disease, but also a positive forcible backward impulse against the advancing current, which necessarily first tells on the large mass of blood in the vena cava and such main branches as the hepatic veins. The impulse may cause the whole liver to pulsate, and anyhow it obstructs the portal circulation, and may thus give rise to ascitic effusion. (I have dealt with this point in my article on the "Pathology and Treatment of Dropsy," in the *Journal* of July, 1886, so need not refer further to it here.) There is urgent orthopnoea, the radial pulse is quick, very small, weak, and irregular. The sphygmograph shows that, while the arterial tension may be comparatively high, only a slight pressure is required to obliterate the pulse; its volume is small, duration short, and many of the beats fail to reach the wrist or are only recorded as interpolated pulsations in the downstroke. The dilated right ventricle struggles ineffectually, but it may be violently, especially if the failure in compensation be due to overwork or acute strain before there is degeneration of its muscular fibre, to perform its task. The action of the heart is tumultuous and the principal impulse over the right ventricle; the rhythm is very irregular, and presents the characteristics to which I have before referred. There may be a single first sound followed by a double second, or sometimes a double first followed by a single or double second sound. There may be a strong impulse of the heart, due to the right ventricle, accompanied by a weak pulse or absent beat at the wrist, indicating a feeble left systole. One or more weak pulse-beats may succeed or be succeeded by a forcible contraction of the left ventricle. When there is almost absolute failure of the right ventricle, with free regurgitation through the tricuspid orifice, this peculiar irregularity of rhythm disappears: there is very little onward movement of the blood; the left ventricle receives little and propels little blood; the right ventricle is well supplied, but drives the greater part back through the dilated orifice; the circulation then almost comes to a stand-still, and eventually the heart ceases to beat.

Even in these extreme cases bloodletting from the arm is generally spoken of and boldly advocated as the *dernier ressort*, but what good it can accomplish, save in the imagination of the operator, I fail to see. You only thus assist

nature in emptying an already depleted arterial system, and so hasten the not far distant end. That the personal equation comes largely into play in observing the effects of treatment there can be no doubt, and in no class of cases more so than those under consideration. The sanguine operator generally thinks he sees the result he expected, and the frightened patient experiences the very temporary relief which he was told would take place. The motto would seem to be "draw blood," it does not matter from where or how, so that verily there would seem to be danger of our falling into the errors of our forefathers.

When the right side of the heart is over-distended, so that it cannot effectively contract, there can be no doubt but that depletion is the most rapid and perhaps best method of enabling it to do so. In an urgent case, therefore, I would have no hesitation in aspirating the right ventricle or right auricle, as suggested by Dr. Westbrook, of Brooklyn. In less urgent cases I would freely aspirate the liver or open the hemorrhoidal veins. The right ventricle should be further relieved by brisk cholagogue cathartics. The action of the heart should be aroused by external warmth, sinapism to the præcordia, ammonia to the nostrils, and the internal use of such remedies as nitro-glycerin with atropine, ammonia, ether, or alcohol, these drugs to be given with as little fluid as possible; when the patient is cold and pulseless, ether and atropine may be injected hypodermically.

When the urgent symptoms have been tided over, it may be necessary to give such cardiac tonics as digitalis, caffeine, convallaria, and strophanthus. As a cardiac tonic, strophanthus is my favorite in mitral stenosis, digitalis in mitral regurgitation, to lessen the size and increase the force of the right ventricle, but they are usually better combined with some agent to lessen and more evenly distribute the work of the heart, such as nitro-glycerin, sweet spirits of nitre, or alcohol. Atropine is a respiratory stimulant, a cardiac tonic, and also lessens peripheral resistance, and in some cases I have found small doses of it, with nitro-glycerin, to answer admirably. It must be remembered, however, that with advancing recovery and diminution of blood in the veins, it is not prudent to greatly dilate the systemic arterioles, which would thus allow too free an escape of blood through the capillaries into the veins, and keep the arterial pressure at a low ebb. About  $\frac{1}{16}$  grain of atropine, combined with a similar quantity of nitro-glycerin, three or four times a day, is usually sufficient; to this may

be occasionally added 5-minim doses of tinct. digitalis or tinct. strophanthi. Ammonia, caffeine, and nux vomica often prove a good substitute. As the case advances towards recovery I have seen a mixture of citrate of quinine and iron, digitalis, and strychnine, given for short intermittent periods, do good service. Convallaria is highly recommended by Dr. Sansom.

It is now more necessary than ever to insist on the general principles of diet and abstinence from liquids which I have previously mentioned. *Massage* may now be used to improve the circulation, but it must not be used to hurry on the blood until the right side of the heart is relieved and the venous system depleted.

I have already incidentally referred to the effects on the liver and the great enlargement that organ undergoes, with subsequent contraction from cirrhosis, resulting from the chronic congestion. These effects are best obviated by limiting the amount of fluid ingested and so lessening the portal circulation, and by the regular employment of cholagogue cathartics.

The kidneys suffer in the general venous congestion, but in the early stages of the disease the arterial tension is good, and hence the renal secretion is free. When failure of the right ventricle with tricuspid regurgitation takes place, the arterial pressure falls, the onward current of the blood is diminished, and the urine correspondingly lessened. As the improvement takes place there is a return to the former condition of affairs, with restoration of the renal secretion. The indications for treatment, therefore, are to improve the state of the right ventricle and that of the left will naturally follow, hasten the circulation, and maintain moderate arterial tension. Diuresis is evidence of improved circulation, and shows that the cardiac tonics are having a good effect.

Bloodletting is a valuable auxiliary in the treatment of heart-disease, and is certain in the near future to be more generally used than it is at present. I rather regret to have to differ in some matters of detail from my sanguinary friends, but I think that the subject of bloodletting is one which admits of free discussion, so that accurate rules may be formulated for the employment of such a powerful weapon—powerful alike for good or evil—in the treatment of disease. We must have a clear conception of the conditions which are benefited by bloodletting, and how, in any given set of conditions, the abstraction had best

be performed. We must know why we bleed, when to bleed, where to bleed, and how much to bleed.

In reading the histories of cases cured, relieved, and supposed to be relieved by venesection, it is often very apparent that the operator has got a very inadequate idea of any elementary principles to guide his action. You may read of a physician opening the median basilic vein, and drawing off perhaps a pint of blood, in a case of very high arterial tension, with immediate and lasting benefit to the patient. In perhaps the next case in which he performs the operation the arteries are almost empty, and it is with great difficulty that he can withdraw a third of the former amount. Yet both he and the frightened patient may imagine that the bloody deed has been fraught with great relief, though very probably the death of the latter may show that there has been no lasting benefit. When the bleeding is limited to such flea-bites as a few leeches, or dry cupping over the liver or præcordia, there cannot be much harm done. I could never see the rationale of abstracting, say, ten ounces of blood from the arm and at the same time putting a pint of warm milk in the stomach. If physicians could only be taught to lessen the amount of liquid ingested in cases where the heart is overburdened with fluid, then venesection might often be dispensed with.

Some time ago I was asked to see a patient who was supposed to be suffering from angina pectoris. He was propped up in bed, and breathing was labored. There was great sense of oppression and pain about the præcordia, which caused him to be very restless, constantly tossing about and unable to get into an easy position. His countenance was anxious and distressed, he moaned and sobbed with anguish, cried for breath, threw his legs out of bed, and could obtain no relief. His liver was much congested, digestive functions disturbed, and bowels confined. His pulse was frequent, large, of good strength, full and bounding; all the veins were turgid, face dusky, mucous membranes livid, skin hot, and perspiring freely. He had been in this condition for about forty-eight hours, during which time he had had no sleep, and the case was now looked upon by those in attendance as well-nigh hopeless. He had been treated for two days with nitro-glycerin, nitrite of amyl, a liberal allowance of brandy, which induced thirst, and this was gratified by a free supply of liquids. I diagnosed the case as one of primary dilatation of the right ventricle from

overwork. As the arterial system was well filled and there was a free supply of blood from the lungs through the left side of the heart, I felt strongly inclined to relieve the right side of the heart indirectly through the lungs and systemic arteries by free bleeding from the arm. However, I decided to give the following method of treatment a trial first. At my suggestion, the alcohol, nitro-glycerin, and nitrite of amyl were stopped and the fluids were much diminished. He got 4 grains of calomel, followed by an ounce of sulphate of sodium, which was repeated after some hours. He soon experienced considerable relief, and towards morning had about two hours' sleep. He progressed very favorably, but before he was quite convalescent he was rather indiscreet in his diet and drink, which brought on a relapse. This was quickly relieved by the same method of treatment. He next got a mixture of caffeine and ammonia, afterwards digitalis and nux vomica, which again were replaced by strophanthus. He was put on a light dry diet, with only about one pint of liquid in the twenty-four hours. He was soon allowed to have exercise, which he was ordered to gradually increase, so that in a short time he was able to do a hard day's work. I have recently learned that he has since kept quite well and strong. I have not the slightest doubt but that bleeding would have done this patient good, but the removal of twenty ounces of blood from his arm would not have been a whit more effectual than the mode of depletion which I adopted.

Regarding nitro-glycerin and atropine (two drugs of which I have spoken highly in the treatment of mitral stenosis), I may say that I always prescribe them in small doses,— $\frac{1}{100}$  to  $\frac{1}{80}$  of a minim of the former and  $\frac{1}{160}$  to  $\frac{1}{100}$  grain of the latter,—sometimes separately and sometimes together, and the frequency of the dose is decided by the effects produced. When I hear of a dose of 10 minims of a one-per-cent. solution of nitro-glycerin having been prescribed, I suspect that there was something wrong with the drug. Sooner than adopt such a practice, I would try a few doses of the mixture on myself, and if the physiological effects were not produced I would change the druggist. I may also remark that in mitral stenosis it is not desirable to reduce the peripheral resistance too low, lest you produce worse effects than those you are trying to remedy.

I could cite numerous cases in support of the contentions in this paper, but it has already assumed such dimensions that I must forbear for the present.

*THE USE OF PILOCARPINE HYPODERMICALLY IN FACIAL ERYSIPELAS, WITH A REPORT OF CASES.*

BY JULIUS L. SALINGER, M.D.,

Lecturer on Renal Diseases in the Jefferson Medical College;  
Chief of Medical Clinic, Jefferson Medical College  
Hospital; Physician to the Philadelphia  
Hospital, etc.

NO disease in recent times has undergone so many ineffectual changes in treatment as has erysipelas. It was hoped that, with the introduction of some of the modern drugs, such as antiseptics, antipyretics, etc., some agent would be found which would successfully combat the disease. Up to the present time the orthodox treatment by iron and its preparations, especially the *tincture* of the *chloride*, has been much in vogue. It can, however, scarcely be claimed that this treatment shortens the course of the disease, as uncomplicated erysipelas is a self-limited malady, which usually lasts from eight to ten days. A remedy, to be operative in a self-limited disease, must either shorten or powerfully influence its principal symptoms. Through the study of the pathology of erysipelas, especially the significance of its causative germ, and the knowledge of its distribution in the economy and the relation that the germ bears to the skin and the general lymphatic system, remedies should be used that have a local or specific action on these structures. It was for this reason that Da Costa introduced the treatment of erysipelas by pilocarpine hypodermically.

Pilocarpine, according to Brunton, stimulates the secreting nerves. In this way an enormous secretion of saliva from the salivary glands is caused. Large secretions of sweat, from its action on the sweat glands, are produced, beginning either in the face or at the point of subcutaneous injection, and thence extending over the whole body. The large amount of sweating produced causes a fall in the temperature, the secretion of sweat usually lasting two or three hours, and is often so copious that the body loses from one to two pounds in weight. Pilocarpine is *excreted* in the urine unchanged by the kidney (Brunton).

It is not the object of this article to call attention to the symptomatology or pathology of erysipelas, but merely to give the result of a number of cases treated exclusively by the hypodermic use of pilocarpine. The cases were not selected, but treated in a series, both in hospital and private practice, numbering, in all, twenty-eight. Of this number, twenty were

males and eight females, the ages ranging from twenty-two to seventy-six.

CASE I.—T. G., aged thirty-eight, black, laborer by occupation, was admitted to Philadelphia Hospital on June 6, 1893. Patient was well nourished and of medium stature. Casual examination showed the face to be swollen and cedematous, the eyelids being almost entirely closed. As the swelling extended upward over the head on both sides, it gradually lessened, but even at the base of the skull there was a boggy sensation on pressure. The swelling also gradually decreased as it extended downward over the face to the neck. Blebs were noticeable on the cheeks and forehead, and some of the cervical glands were enlarged. The margin of the eruption was raised and well defined; the nose distorted and the ears shapeless; the skin was hot to the touch. Physical examination showed the heart and lungs normal. The patient appeared dull and stupid, answering questions hesitatingly, seeming not to comprehend them. His wife said that two days before having been brought to the hospital he became engaged in a street-brawl, while under the influence of liquor. In the fight he received an injury above his right eye, which appeared to heal rapidly, but which later proved to be the starting-point of the erysipelas. On admission to the hospital, he soon became delirious; his temperature taken in the axilla was 104° F.; his pulse, 108, feeble, and thready; his respiration, 24. His face was dusted with bismuth subnitrate and a mask applied. He was given a hypodermic of  $\frac{1}{6}$  grain of pilocarpine. In three hours, noticing that no sweating had taken place, the hypodermic was repeated. The temperature fell slightly during the night; towards morning it again rose, and the patient became very delirious, attempting to get out of bed, and making considerable noise, etc. An examination of the urine showed specific gravity 1015; albumin was present, both by the ring and heat test, in appreciable amount; casts were not found. The hypodermics were given every four hours. After the third injection a small amount of sweating was noted. The delirium increased, and it was necessary to strap him down on the bed. On the evening of the next day the temperature dropped to 101° F. He fell asleep, and was much quieter during the night, although still slightly delirious; in fact, delirium was present for the next two days to a greater or less extent. During this time the sweating was most copious. On the fourth day a pseudocrisis occurred. The eruption, which had been gradually improving, had nearly disappeared.

On the night of the same day a fresh invasion of the disease above the right eyebrow sent the temperature up again. The hypodermics were again used; but two were given, and towards morning the temperature was again normal. He remained in the hospital a week longer, during which time the temperature remained normal. On the sixth day the inflammation of the skin over the face and scalp, which was most extensive, had entirely disappeared. Desquamation was quite marked over the inflammatory area. The albumin had entirely disappeared from the urine. This was the only treatment, with the exception of six ounces of whiskey, given in the course of twenty-four hours, in divided doses.

This, undoubtedly, was an exceptionally severe case, the temperature being higher, the delirium more marked, the eruption more extensive than in average cases. The quantity of albumin present was a guide by which to judge of the severity of the case, for although traces of albumin are present in ordinary cases, large amounts always signify extensive disease. The writer has reported a case (*Medical News*, July, 1891, "Renal Disease and Uræmia attending Acute Facial Erysipelas") in which lasting renal disease was the result of facial erysipelas.

Notwithstanding the severity of the symptoms in the above-quoted case, the disease lasted only six days, and the almost immediate amelioration of the symptoms was unquestionably due to the administration of hypodermics of pilocarpine.

Case II. shows a somewhat rarer form of erysipelas, and one which, under ordinary circumstances, is not so easily influenced by treatment.

CASE II.—S. S., white, laborer, native of Russia. A history could be obtained only with great difficulty, as the patient spoke Russian. On admission to the hospital his temperature was 103° F., his pulse 88, his respirations 36. He was a powerfully-built man, of fair complexion. When first seen, his face had a dusky, red hue, but there was no evidence of any present inflammation. Attached to his ears were pieces of dried, loose skin, as though they were remains of blisters. A circumscribed area of redness was visible in the left pectoral region, extending through the axillary space to the back. The dull color of the neck and shoulders and the particles of dry skin gave evidence of previous inflammation. Passing downward, the skin was seen to assume a much brighter hue, and was extremely hot to the touch. A distinctly marginate appearance, slightly elevated, was apparent. The pos-

terior surface of both arms was affected, this process extending towards the flexor surface and almost completely encircling the arm. Posteriorly, the process extended almost to the lumbar region; the familiar picture of erysipelas migrans was easily demonstrable. Physical examination gave no evidence of disease. He frequently brought the hand to the forehead, showing that he suffered greatly from headache.

He was given a hypodermic of  $\frac{1}{6}$  grain of pilocarpine. After the first hypodermic the temperature fell during the night, till at eight o'clock the next morning it was 97.3° F. The man had perspired very profusely. Later in the day the temperature rose to 99° F., but he seemed very comfortable. He had applied a paste of bismuth subnitrate and water to the inflamed area, which appeared to exercise a very beneficial influence. At first the man suffered from retention of urine, voiding none at all the first day, until after the use of the hypodermic, when a small quantity was passed. The urine contained traces of albumin; no casts. The next day he voided only eight ounces; by catheter twenty-seven ounces more were obtained. On the third day the quantity of urine was normal. The hypodermics of pilocarpine were given every four hours, there being usually a fall of from  $1\frac{1}{2}^{\circ}$  to  $2\frac{1}{2}^{\circ}$  F. after its administration.

The process extended almost over the entire anterior surface of the chest and over the arms to the elbows. The erysipelatous process improved at once after the administration of the hypodermics, and by the fourth day nothing could be seen except blebs and dry skin where the process had been. In this case there was no delirium, and, with the exception of headache, the patient seemed fairly comfortable. Indeed, the headache remained as a troublesome symptom for nearly one week after all traces of the inflammation had disappeared.

From the appearance of the face, ears, and neck of the patient it could be fairly assumed that the disease must have begun as one of facial erysipelas, and must have existed for at least a number of days before the patient's admission to the hospital. No trace of a wound or injury could be found.

The histories narrated above are each a type of severe erysipelas encountered mostly in hospital practice. In Case I. most likely the alcoholic history was in large part responsible for the amount of delirium present, for it is well known that when drunkards are attacked with acute diseases, delirium is always a prominent symptom.

In all the cases treated by this method (twenty-eight), the disease was comparatively severe. In none did the treatment last longer than eight days, and quite a number recovered in four days. Albuminuria, to a greater or less extent, was present in twenty-six cases, and lasted throughout the course of the disease. In the severest cases quite appreciable amounts could be obtained by the cold test with nitric acid. In none of the cases were tube-casts present. Four of the patients suffered from retention of urine.

The good results obtained by pilocarpine must be ascribed to its action on the skin and subcutaneous tissues. Perhaps the sweating induced by its administration opens a passage for the expulsion of the bacilli which are responsible for this disease. Certain it is that larger quantities of urine are passed and retention rapidly relieved by pilocarpine. The advantage of administering pilocarpine hypodermically is to be found in its rapid action. In order to obtain the best results, the full physiological action of pilocarpine must be produced; that is to say, that unless marked sweating, increased salivation, and increased diuresis are noticed, good results will be looked for in vain.

The only contraindications to its use would seem to be in cases of actual organic disease of the heart. Where cardiac disease is present, pilocarpine may have entirely too depressing an effect upon the circulation, nor would it be a safe remedy for old, enfeebled, and cachectic persons. When erysipelas occurs as a complication in another disease, pilocarpine has not shown itself to be effectual. It seems that, where erysipelas occurs as a secondary disease, the process is more severe. Hence so-called idiopathic erysipelas is the only form of the disease in which pilocarpine may be safely and advantageously administered.

#### ANÆSTHESIA. THE TECHNIQUE OF CHLOROFORMIZATION.

A PAPER PRESENTED TO THE SECTION ON THERAPEUTICS OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS, HELD IN WASHINGTON, SEPTEMBER 5, 6, 7, AND 8, 1893.

BY ANGEL CONTRERAS, M.D.,

Professor of Clinical Surgery in the Medical School of Puebla;  
Delegate from the State of Yucatan, Mexico.

to treat so important a subject,—a subject that can be elucidated by abler men only. I hope a discussion of the matter will tend to bring about a uniformity of opinion regarding the best means to employ in the production of anæsthesia without danger to human life.

Science seeks the discovery of a harmless anæsthetic. The best methods for the production of local loss of sensibility are at present occupying the minds of investigators.

The most powerful procedures wrought by the real progress of modern surgery, especially during the nineteenth century, may be said to be three,—anæsthesia, antiseptis, and hæmorrhage, this latter being the complement of the first two.

Soubeiran discovered chloroform in the year 1831 among the chemical products of the methylic series.

History tells us that on the 14th of October, 1846, Morton produced anæsthesia with ether before a large number of physicians and medical students in Boston, upon a patient from whom Warren removed an enormous tumor of the neck without causing the least pain. A year afterwards, Simpson and Flourens, in memoirs presented to their respective academies, proclaimed the anæsthetic properties of chloroform, and from that date the employment of this agent has become general, like everything else that is found really useful.

In the republic of Mexico, which I have the honor to represent as one of its delegates in this Congress, Dr. Miguel Jimenez made use of chloroform at that time for the production of anæsthesia upon soldiers who defended the independence of the country against the American invasion.

From its very cradle chloroform has been the rival of ether as an anæsthetic agent, and up to the present day one remedy has won no special victory over the other, a proof that both are good, although the observer generally praises higher that anæsthetic which he has most employed.

We Mexican physicians are in the habit of using chloroform almost exclusively.

At a height of two thousand two hundred and seventy metres above the level of the sea, at which the valley of Mexico is situated, ether is too volatile to be of much use, and, more than in other parts, special apparatuses are required for its administration.

It is generally admitted that chloroformization is obtained more rapidly than etherization; that its effects are more intense and durable; that the excitation produced is less; that the vapors of chloroform are not inflammable, nor do they provoke so much salivary

WE owe a debt of gratitude to the immortal names of Soubeiran, Simpson, and Flourens for the great discovery of anæsthesia by means of chloroform. I have thought it proper that these should be the first words uttered by me before this learned body, and I beg to be excused for any shortcomings in my endeavor

and bronchial secretion as those of ether; and that, finally, the latter remedy is apt to produce a tardy cardiac syncope, while the same phenomenon generally occurs, when it does come, at the very beginning of chloroform anæsthesia. It seems to me, however, that in order to establish a preference between the two agents, the percentage of mortality produced by each one of the two remedies should be taken into consideration; but here, again, serious difficulties are met with. The cases upon which the two anæsthetic drugs are used are not always of the same nature, and cannot therefore offer a basis which should be the starting-point for the formation of a more or less accurate opinion regarding the danger of either medicament. Again, chloroform appears to be more widely employed than is ether; and, finally, not all the unfortunate cases have ever been published. The percentage of death recorded so far, and attributed directly to the use of ether and chloroform respectively, becomes worthless, and from it no definite opinion can be formed as to the degree of danger peculiar to one or the other agent.

According to the researches of Arloing, it may be inferred that ether is preferable in certain cases,—that is, in those individuals suffering from disease of the right heart; while chloroform is safer for those patients affected with disease of the left heart, and, according to Duret, when there is present a simple ventricular atony. Some practitioners believe that in cases of strangulated hernia ether should be preferred, from the fact that chloroform has a tendency to cause pulmonary hypostasis and a dangerous dyspnea.

I will not dwell on how chloroform acts, neither will I endeavor to explain the phenomena produced by the drug, with reference to the abolition of the functions of the cerebrum, medulla oblongata, and spinal cord, bearing in mind that the science of chloroformization consists mainly in one being able to give a sufficient amount of the remedy to cause loss of sensibility, without producing paralysis of the heart or the respiration.

It cannot be denied that any time during the process of chloroformization sudden death of the patient may supervene.

It was at first believed that ether was exempt from causing this fatal issue, and it is said that Hayward travelled all over Europe bent especially on the discovery of a single death produced by that anæsthetic. But time has shown that not only one but several cases of death have occurred under the administration of ether.

Reputed authorities, like Sedillot and Gosselin, have affirmed that pure chloroform, carefully administered, is incapable of causing death. But I believe that the consensus of opinion at present is that, notwithstanding the purity of chloroform and the ability of the anæsthetizer, a fatal issue may take place.

It has also been established that death may occur under circumstances traceable to the mode of administration of the anæsthetic, and hence the importance attached to the technique in the application of chloroform. To this technique I wish especially to call attention, since each one of us, as a rule, will follow the procedure towards which he is inclined or to which he has been accustomed. As showing that death under anæsthesia is exceptional, I remember having read that Billroth met with a single fatal case out of twelve thousand five hundred individuals anæsthetized with chloroform. It is, therefore, of the utmost importance that eminent practitioners, surrounded by the halo of a vast experience, should endeavor to establish the best means of producing anæsthesia without danger to the patient.

For a long time, I believe, the method of interrupted inhalations and strong doses was generally employed. One or two grammes of chloroform were poured into a common cone, this being placed over the nostrils and mouth of the patient, allowing at the same time a free access of air. The cone was gradually brought nearer the patient, the quantity of the drug increased, this being renewed when the evaporation of the chloroform was thought to be complete. The cone was then removed for a short time, to be refilled with more anæsthetic and reapplied, the manœuvre continuing as long as it was believed to be necessary, so that the amount of the liquid and the time employed in the application of the interrupted inhalations were left to the discretion of the anæsthetizer.

The method of continuous inhalation was first proposed by Labbé in 1882. In this way the nerve-centres are not suddenly but gradually acted upon, and thus fatal accidents are largely avoided. Time and chloroform are also economized.

Dr. Miguel Cordero (died this year), of the city of Mexico, presented to the Academia Nacional de Medicina, in January, 1890, and in the same month of 1891, memoirs in which he advocated the method of rapid anæsthesia by chloroform inhalations. This method he had found of undoubted value in a large number of observations.

His procedure consists in a continuous inhalation, pouring the chloroform by drops over a handkerchief or any other piece of linen, which he never allowed to be taken away from the face of the patient, permitting, at the same time, a free access of air. Before the first few drops were completely evaporated new ones were poured over.

I will here transcribe the technique of Dr. Cordero, as described by him on page 122 of vol. xxv. of the *Gaceta Médica de Mexico*: "The apparatus is simple enough; there is nothing special in regard to its construction. Sometimes a layer of cotton fixed over a wire screen is used, sometimes Esmarch's apparatus. Usually, however, the simple cone made of coarse cotton linen, with a sufficiently large aperture on the top to permit free access of air, is employed. No cotton or any other material is placed within the cone; this is allowed to remain empty, and it is over the external surface of the cone that the chloroform is poured in small quantities at a time.

"When the first drops of the liquid are poured on the cone, this is brought over the mouth and nostrils of the patient, but without touching those parts, in order that the air may also find entrance in this way. These first drops produce upon the linen of the cone a stain which does not disappear until evaporation has completely taken place; but before this occurs (which it usually does in the course of a few seconds), new drops of chloroform are poured. The procedure is continued until the disappearance of the palpebral reflexes and complete loss of movement in the patient show that full anæsthesia has been established, when any operation can be performed without the causation of pain. If during the administration untoward phenomena are observed, no matter how slight, the inhalation should be stopped immediately. During the operation, under full anæsthesia, the administration of the agent should be continued as before, employing less quantities, and even adopting, under these circumstances, the interrupted plan until the end of the operation."

According to the observations of Dr. Cordero, no fatal result was recorded under the employment of chloroform by the above method. Anæsthesia was produced in from six to eight minutes, and the amount of chloroform used was 18.60 grammes. The average time employed in the operative acts was 18.6 minutes.

These results are very satisfactory when compared with those obtained by other methods of administration. They are especially worthy of attention, from the fact that in Mexico it was

noted, previous to that time, that with the use of chloroform in large doses, administered in an interrupted manner, a longer time was required to produce anæsthesia than in Europe with precisely the same method.

This difference gave rise to a spirited discussion. Some attributed such difference to the considerable height at which the valley of Mexico was situated, because, according to Dr. Ramos, who spoke before the Academia de Medicina, the rarefaction of the air enhances the evaporation of volatile liquids like chloroform, in which case, though an equal volume of air is inspired, a relatively less amount of the anæsthetic is taken in by the lungs. Others thought that the difference lay in the kind of chloroform used (although the agent generally preferred in Mexico is the one furnished by a certain reliable English firm); while still others attributed the phenomenon to the method employed in the administration of the chloroform. The observations of Dr. Cordero appear to sustain the latter opinion.

In the Hospital General of the State of Puebla, which, as Professor of Clinical Surgery, I have under my immediate charge, I have for the last few years employed the method proposed by Dr. Cordero, and been able to confirm his observations. In the same hospital one of my colleagues has also lately used the method of continuous inhalation; but in this instance he uses a larger amount of the drug, and applies the cone firmly over the mouth and nostrils of the patient, without allowing a free access of air. This modification is known among us under the name of "the method by assault." The two thumbs hold the superior angles of the cone against the cheeks, and the two index-fingers the inferior angles of the cone against the ascending rami of the inferior maxillary bone, this bone being, at the same time, pushed forward. The cone is never removed, while over it the chloroform is constantly poured, and in large amounts. The truth of the matter is that the results obtained by this method are rapid, and no excitement is produced even in alcoholic patients. Yet asphyxia and cardiac failure are to be feared during this procedure, since the susceptibility of the individual to chloroform can only be measured by the gradual administration of the drug.

Dr. Bolognesi, of Mans, has lately applied chloroform in small doses and by continuous inhalation, the patient being placed in an inclined plane of forty-five degrees. This method has been used especially in cases of laparotomy. So happy have been the results (particularly with regard to the cerebral congestion deter-

mined by this position) in the march and excellence of chloroformization, that the procedure of Bolognesi might become generalized in the practice of other operations.

According to that author, the congestive phenomena determined in the encephalic mass prevent the occurrence of cardiac syncope (this is the most dangerous accident to be feared during the administration of chloroform), while the respiration may be interfered with through mechanical phenomena, which can easily be obviated by the use of a tongue forceps, the propulsion of the inferior maxillary bone, and the employment of the inclined table.

Regarding the accidents produced by chloroform, I will only repeat here what my compatriot, Dr. Hurtado, has said briefly but to the point: "Only those phenomena which come on gradually can be combated and even avoided; but those which occur suddenly can rarely be dealt with in a satisfactory manner, since, as a rule, they give no time in which to prevent them, much less in which to combat them."

#### UNUSUAL MORBID GROWTHS IN THE NOSE AND MOUTH.

CLINICAL NOTES.

BY W. S. JONES, M.D.,  
Chief of Throat Department of the Jefferson Medical  
College Hospital.

**T**HERE are here recorded three cases, two of which were carcinomata of the turbinated tissues. To the date of this report there have been no signs of recurrence in either. This suggests that many cases may be curable if taken at the commencement of the disease, provided the growths are properly and thoroughly removed.

came partially closed. It extended over the malar bone. The right nostril was occluded, and finally completely obstructed. Marked epiphora existed. Examination disclosed occlusion of the nasal duct by a large growth, involving the inferior and middle turbinated bones. A portion of this growth was removed and examined by Professor Coplin, who pronounced it to be carcinoma.

One week later the cold snare was applied to as much of the growth as could be caught; it was made to cut through slowly, very little blood being lost.

Three days afterwards examination showed that a large part of the growth remained. This was too inaccessible for satisfactory snaring and too extensive for cauterization. I devised a curette to meet these conditions, which is shown in the cut. It has a sharp cutting edge. With this instrument all of the growth and a certain amount of the apparently healthy surrounding tissue were removed. Hemorrhage was severe, but stopped spontaneously. As soon as it ceased lactic acid was applied to the site of the tumor. Two more applications of acid were made during the next week, and the nose was washed out daily with peroxide of hydrogen. In two weeks after the operation the parts were healed. There was no recurrence up to the date of this report (eighteen months).

**CASE II.**—Mrs. S., aged forty-three. Lost her father from cancer of the stomach. Her symptoms were similar to those of the previous case. The right side was affected, and there was epiphora, together with occlusion of the nasal cavity. The operation was performed two weeks after the former case was subjected to radical treatment. The diagnosis was confirmed by the microscope. There was no return after one year.

While carcinoma and sarcoma are unusual affections in the nose, they occur with sufficient frequency to warrant the specialist making a careful search for them when symptoms and signs point to tumor formation.

**CASE I.**—*Carcinoma of the Turbinated Bodies.*—W. S., aged thirty-four, presented himself at the Out-Patient Throat Department of the Jefferson Medical College Hospital. His family history and his general health were good. Three months before applying he detected a small swelling on the right side of his nose. This increased in size until the right eye be-

**CASE III.**—*Ossifying Fibroma of the Alveolar Process.*—Miss R. H., housekeeper, aged thirty-six, applied to the clinic February 8, 1893. Examination disclosed a large, dense; thick growth which covered the entire area of the palatine processes of the superior maxillary and palatal bones and pushed back the soft palate. It extended from a thick pedicle which was attached to the alveolar process opposite the molar teeth of the right side.

The patient stated that she first noticed this growth ten years ago, when it was about the size of a Lima bean, and that it had ever since

progressively increased in size, without pain and without any particular discomfort, except lately difficulty in eating.

This tumor was found to have adapted itself to the shape of the bones, so that it much resembled the contour of the human ear. It was covered with healthy mucous membrane, and was very hard to the touch, feeling like bone. The exploring-needle showed that the tumor was hard upon its surface, but was soft in its interior.

On February 10 a twenty-per-cent. solution of cocaine was applied, and Professor Cohen removed the growth with the incandescent snare.

The fine wire of the electric cautery was passed around the pedicle and tightened, and then the current was turned on to a dull-red heat. Resistance at first was not great, but as the wire neared the centre of the growth this increased to such an extent that the wire, though of steel, was broken. Another and larger wire was applied, and then the tumor was easily cut through in about five minutes, care being taken to operate slowly.

The pedicle of this tumor contained bony spiculæ, which projected into the substance of the tumor for fully one-fourth of an inch.

The wound was treated daily for one week with a solution of pyoktanin, when the patient was discharged cured. This tumor has had no counterpart in my experience of ten years in the hospital.

#### THE ACTION OF THE HYDROCHLORATE OF SCOPOLAMINE ON THE EYE.

READ BEFORE THE NEW YORK STATE MEDICAL SOCIETY,  
FEBRUARY 7, 1894.

BY THOMAS R. POOLEY, M.D.,

Permanent Member of the Medical Society of the State of New York; Surgeon-in-Chief of the New Amsterdam Eye and Ear Hospital; Professor of Ophthalmology in the New York Polyclinic.

IT is the purpose of this paper to briefly summarize some of the observations already published in relation to this drug, and then to give the writer's experience with the same for the past six months.

In the *Klinische Monatsblätter für Augenheilkunde*, xxi. Jahrgang, February, 1893, Raehlmann publishes a paper, in which he says that A. Schmidt, of Marburg, first described this drug,—an atropoid alkaloid derived from the roots of the *Scopolia atropoides*, and which, like atropine, hyoscine, etc., belongs to the pharmacological group of the tropeines, and as such the instillation of a watery solution in the eye causes dilatation of

the pupil. According to Landenburg, scopolamine, as well as hyoscine, are contained in hyoscyamus, without being identical with the latter. It is rather isomeric with cocaine, but yields quite different integral products.

The preparation was given to Raehlmann by Professor Kobert, with the information that, after experiments on the lower animals by the internal administration of scopolamine, it showed an opposite effect to atropine, and that its influence on the cortex of the brain was not stimulating like that of atropine, but, on the contrary, retarded its action. (Later on I shall have some comments to make on the erroneous character of these observations.) These last-named qualities led to the expectation *a priori* that the local special effects of the new remedy would be different, especially on the conjunctival blood-vessels. Raehlmann, after using scopolamine both on normal and diseased eyes, came to the conclusion that as a mydriatic and antiphlogistic it surpasses all other tropeines, including atropine. In strength of mydriatic effect it resembles hyoscine closely. The remedy does not produce the disagreeable after-effects and double vision which, according to his observations, occur with hyoscine; but it possesses all the advantages which belong to hyoscine in comparison with atropine. He used it during a period of six months in all cases in which atropine is applicable, and also by way of comparison with atropine, and has found that scopolamine is, in many cases at least, equal to atropine, while in others it is its superior. According to Raehlmann, the property which will insure scopolamine an enduring place among ophthalmic remedies is that it can be used for a longer time in a solution equivalent to a one-per-cent. solution of atropine without producing the troublesome associated symptoms which so often make the continued use of atropine impossible. He further says—but this I do not believe—that it is well known that atropine, when used as an instillation for any length of time, disturbs the appetite. He has never seen this or similar effects from the use of scopolamine. It is only after very large doses of scopolamine that a feeling of dryness of the throat is produced, a symptom which occurs after a very moderate dose of atropine. The state of nervous restlessness, with or without reddening of the face and quick pulse, which is so often found in patients treated with atropine, never occurred after the use of scopolamine. In cases of incipient atropine-poisoning, or in an idiosyncrasy towards atropine, scopolamine renders, therefore, the best service, since it more than sup-

plants atropine in its local effect and completely obviates general effects.

In cases of iritis, episcleritis with infiltration of the sclerotic, etc., when atropine could not be any longer endured, when the powers of the body were depressed on account of want of appetite, and the general condition of the body was as unfavorable as possible, scopolamine not only improved the eye-disease, but also the general health. The remedy surpasses atropine in its influence on peri-corneal injection, and possesses special advantage in suppurative keratitis, serpent ulcer, and irido-cyclitis. As is known, under these circumstances, especially in suppurative keratitis, serpent ulcer, and irido-cyclitis, atropine is often inadvisable; but Raehlmann has found in five cases that scopolamine caused a diminution in the size of a hypopyon. Scopolamine seems to act far more favorably on suppurating tissues than atropine, probably through its effect on the blood-vessels. Scopolamine does not seem to elevate intraocular pressure, even if there is a pathological increase of tension. If there is a pathological increase of tension, the remedy can be borne; therefore it is an indispensable drug in inflammatory conditions, especially in iritis, when they occur in glaucomatous eyes. He has used scopolamine with advantage in several cases of chronic inflammation with secondary glaucoma. In one case of absolute glaucoma with great irritation, strong ciliary injection, and hyphæma, the pain ceased, the eye became quiet, and the blood disappeared from the anterior chamber under the influence of this drug. He has not tried it in acute glaucoma.

Hydrochlorate of scopolamine acts five times as powerfully as atropine. It paralyzes, like the latter, and in the same degree, the sphincter of the iris and the accommodation. The duration of the effect—one-fifth per cent. scopolamine compared with one per cent. atropine (whether homatropine or sulphate is not stated)—is about the same, perhaps somewhat shorter with scopolamine than with atropine. It is to be used in solutions of one to two *pro mille* (one tenth to one-fifth per cent.), which solutions correspond in dose to one-half- and one-per-cent. solutions of atropine; 6 to 7 drops may be used daily in an adult, or it may be used every fifteen minutes during one or one and a half hours. With children, correspondingly weaker solutions are to be used. It operates best when used in divided doses.\*

L. Bellarminow† also has some observations on the action of scopolamine, from which he draws the following conclusions, which are essentially the same as those entertained by Raehlmann:

Scopolamine is indicated for the same cases as atropine, especially to determine the anomalies of refraction and accommodation, owing to its marked effect on accommodation, which permits of a speedy and accurate determination; in addition, it considerably shortens the period of duration of paralysis of accommodation and mydriasis. Scopolamine is also preferable to atropine in cases of short attacks of inflammation of the cornea. In general, scopolamine has all the good effects of atropine without its bad qualities. The author, therefore, thinks scopolamine will soon replace atropine in the practice of ophthalmology. Merck‡ describes scopolamine hydrobromate as a salt of the alkaloid from *Scopolia atropoides*, similar in physiological action and use to atropine, but not causing dryness of the throat, nervous restlessness, or congestion of the face, as in the case of atropine; neither does it affect intraocular pressure. Its application as a mydriatic is in one-tenth- to one-fifth-per-cent. solutions, which correspond to one-half- to one-per-cent. atropine solutions.

It was shortly after reading these *couleur de rose* reports of the virtues of the new drug (August, 1893) that I began its occasional use, at first to determine whether it had any local anæsthetic properties, which I soon found it did not possess. I then began its use in all such cases in which we usually employ atropine. The preparation I first used—a one-fifth per cent.—was made by Merck. In all cases where instillations were used by myself or my assistant, Dr. W. J. Killen, this preparation was employed; but when it was prescribed the patients obtained the drug which was stated to have been Merck's preparation from a trustworthy apothecary.

As a mydriatic to determine the anomalies of refraction, my house surgeon has used it in a number of cases, which I will not weary the Society by reporting in detail, but I will briefly give the results. In some instances the instillations were made while the patient was in the hospital,—four times within an hour, or at intervals of fifteen minutes,—and then the examination was proceeded with. In every instance it was found that the effect had been to produce complete paralysis of accommodation, and that mydriasis was produced in from ten

\* Report on Therapeutic Progress, THERAPEUTIC GAZETTE; extract from the *American Journal of Ophthalmology*, July 18, 1893.

† *Wratch*, No. 17, 1893; abstract in the *Revue Générale d'Ophthalmologie*, July, 1893.

‡ The market report for December, 1893.

to fifteen minutes, but that it took about three to four instillations to complete the paralysis of accommodation. The completeness of the paralysis of accommodation was shown both by the inability to see in the near, and by the bringing out in the second examination the total amount of ametropia. The duration of the mydriasis and the paralysis of accommodation was from twenty-four to forty-eight hours,—about the same as homatropine, but much shorter than that of sulphate of atropine. One remarkable result observed by Dr. Killen in several cases was a notable diminution in the visual acuteness after the full effect of the drug on accommodation,—*i.e.*, the correction of the ametropia did not bring the vision to the normal standard.

In three cases, all of them occurring in patients who had bought the drug themselves and used it at home, very marked toxic effects occurred. One of them is so remarkable that I shall take the liberty to report it in full. It happened in a girl of about thirteen years, in whom there was a history of convalescence from nephritis following an attack of diphtheria and cardiac palpitation. These facts, however, did not come to light until after the drug had been used. On January 29, 1894, she came to the clinic, having used the solution of scopolamine (one-fifth per cent.) six times in each eye, when the most alarming symptoms set in: the child began to stagger, talk in a thick, drunken, and foolish way, and at times seemed out of her head, and was very dizzy. At the clinic the pupils were found to be widely dilated, there was constant working of the lips and muscles of the face; the pulse was very rapid,—120 to 130 per minute,—and the heart's action very irregular and rapid. She had a staggering gait, which did not allow her to walk without assistance. She complained of needles under her feet on standing; she said there was dryness of the throat, but there was no erythema of the face. She was kept in the hospital for three hours before she was able to go home. She was given half an ounce of brandy two or three times. Two days later the mother brought her back to have the examination of the eyes completed. She said that all that night the girl raved and was out of her head, and it was only two days after the use of the drug that she seemed to have fully recovered. Two other cases came under notice only a day or two later, both occurring in healthy adult females, in whom the symptoms were the same, but less in degree. In addition, both of these complained of dryness of the fauces. Here, too, the toxic symptoms did not pass off

before twenty-four hours in one case and in the other forty-eight hours. In all of these cases, as the drug was given to be used at home, and a larger quantity prescribed than was needed, more than one drop may have been used, and it may even have run over the face into the mouth. At all events, it seems significant that these symptoms occurred only when the drug was used by the patients themselves. The number of instillations, too, were more than were used at the clinic.

The other cases in which I have used this drug have been mostly in ulcers of the cornea of different types. In one case of serpent ulcer, just the kind in which it is said to be so efficacious, it was noted that scopolamine was used for two days, but the eye was so irritated by it that atropine had to be substituted. In all other affections of the cornea in which it was used there was a very beneficial effect noted, especially so in one case of suppurative keratitis of traumatic origin, in which the healing occurred in a few days. In quite a number of cases of phlyctenular keratitis, too, it acted very promptly. In one case of kerato-iritis the mydriatic effect of the drug was very quick, marked, and satisfactory. I have not yet tried it in cases of iritis of severe type, or in any case in which there was a tendency to increase in intraocular tension, and consequently cannot confirm or deny the very important observation made by the authors quoted, that it does not increase intraocular tension. If this shall be confirmed, however, by future experience and observation, we shall have a drug of inestimable value in ocular therapeutics. I am anxious, too, to try it in cases in which atropine produces the severe form of conjunctivitis which we call "atropine-poisoning," for, from the positive statements made, we may hope that it will not only supersede atropine in these cases, but will also have a favorable effect on its cure when it has already occurred.

My conclusions, then, from my brief trial of scopolamine are: That it is of value as a mydriatic and cycloplegic in the examination of anomalies of refraction; that its action is more complete than homatropine and of about the same duration, and better than sulphate of atropine, because its effects pass off sooner; that it is open to the objection, if my observation should be confirmed by wider experience, that it produces toxic effects oftener than homatropine, in spite of statements to the contrary; that the temporary amblyopia sometimes induced does not seem to be of much moment; that in cases of short attacks of inflammation of the cornea, especially

in some of the suppurative type, it is of special value.

The tendency of the profession to vaunt the therapeutic value of a new drug is well known, and many instances in which those who were loudest in their praises of it soon became equally pronounced in their condemnation must occur to all of us. That scopolamine, as we have quoted from one of the authors, will soon replace atropine in the practice of ophthalmology is not so well assured, but that it may prove a very valuable addition to the list of mydriatics which we now have seems to be altogether likely, and we await with interest further details of experience and observation from our colleagues.

#### THE USE OF METHYLENE BLUE IN MALARIAL FEVER.

We have already published in previous numbers of the THERAPEUTIC GAZETTE interesting abstracts of the employment of this substance in paludal disease. In the *Indian Medical Gazette*, MARSHALL and GEE contribute a short article upon this subject.

During the past two years they have made an extensive trial of methylene blue in the treatment of malarial fevers, on both European and native cases, and from the results obtained are of opinion that in many cases it is a valuable remedy, and that its therapeutic properties deserve wider recognition. Ehrlich has used the drug in a few cases in Germany, and found that the development of malarial plasmodia in the blood was arrested and their number quickly reduced by its administration.

The dose used by the writers in all cases was 2 grains, given as a pill in combination with extract of gentian or hyoscyamus, the latter drug being indicated in cases where the exhibition of methylene blue was followed by symptoms of irritation of the bladder and rectum. One pill was given every two hours, with a maximum number of five during the day.

They found, as a rule, that after the temperature had fallen to normal the amount given could be decreased daily and finally discontinued about the fourth day; also that it was seldom necessary to administer the maximum amount for more than three days.

Their experiments with methylene blue have all been made in Beloochistan, where the prevalent fever is of a type peculiar to itself and is not generally ushered in by a cold stage, the onset of fever being usually sudden and manifested by rapid rise of temperature, accompanied with headache and muscular pains,

pyrexia usually continuing for several hours and the sweating stage not marked.

In these cases quinine and antifebrin frequently fail to check the progress of the disease; while, on the other hand, the administration of methylene blue is often followed by most satisfactory results, the temperature falling to normal in a few hours, and the progress of the disease in many cases being completely arrested.

In some cases of remittent fever, characterized by persistent high temperature and unaffected by the ordinary remedies, the results obtained by the use of methylene blue were immediate and lasting, but in other cases of the same character it did not produce any beneficial effect.

The use of this remedy is occasionally followed by more or less marked symptoms of irritation of the bladder, and also, in a few cases, of the rectum, which can usually be combated by the exhibition of hyoscyamus and potassium bromide, though in two cases the vesical irritation was sufficiently severe to cause retention of urine. The most striking and immediate result of a dose of methylene blue is the change in color of the urine, which generally within two hours assumes a deep blue; in cases where vomiting occurs the vomited matter is also deeply stained; patients are often much alarmed by these appearances and should be forewarned. As the result of their clinical investigations on this subject, they have arrived at the conclusion that, though not a specific in all cases of malarial fever, we possess in methylene blue a therapeutic agent of great value in many cases which resist the ordinary methods of treatment, and deserving a more extended trial, which, we trust, it may receive at the hands of some of the readers of this journal.

#### THE MICROBICIDAL ACTION OF GAL- LANOL.

P. CAZENEUVE, ROLLET, and NICOLAS (*Lyon Medical*) have studied experimentally the microbicidal action of gallanol, drawing the following conclusions:

1. Gallanol in excessive quantities completely arrests the life of micro-organisms.

2. Gallanol in weak solutions (.1 in 100) arrests or diminishes the vegetability of some microbes, leaving other germs intact.

3. Gallanol in very weak solutions (2 in 10,000) does not arrest the vegetability of micro-organisms, although their pathogenic power is almost wholly destroyed.

### THE UNTOWARD EFFECTS OF HYOSCINE IN ACUTE ALCOHOLISM.

UPON the introduction of hyoscine as an hypnotic in 1885 it was hoped that its sphere of application would be very wide, and that it would influence a large number of obstinate cases of insomnia in various types of disease where other older remedies had failed. The experience which has been gained year by year in regard to its influence seems, however, to show us that its sphere of usefulness is exceedingly limited. Even in the type of cases for which it has been most highly recommended it frequently fails,—namely, those of acute mania,—and in many other instances of insomnia associated with fever, doses which are large enough to have any effect whatever simply increase or produce delirium. In the insomnia following acute alcoholism it was thought at one time

that hyoscine would prove of value, but cases are continually occurring in which the administration of the drug has produced such symptoms that it is evident it should never be used for this purpose. In our experience the most alarming but apparently ultimately fortunate symptoms have been developed in the nervous excitement following debauch; and in the *Medical Record* for July 29, 1893, Fiske reports a case in which he administered hyoscine to a patient of about forty years of age. He was exceedingly nervous, sleepless, and restless. His articulation, which, prior to the use of the drug, had been clear, became exceedingly husky and indistinct. His walk became tottering, and finally he fell. His speech was confused and difficult. Sleep never came to his relief. The respiration was slightly irregular, labored, and the entire effect of the drug was distinctly unfortunate. It is only just to the drug, however, to state that Fiske administered too large quantities; while he administered  $\frac{1}{100}$  of a grain hypodermically as the first dose, he administered other doses hypodermically as much as  $\frac{1}{10}$  of a grain. This latter dose is so enormous for this powerful drug that we do not wonder that he developed additional disagreeable symptoms after its use. In one of the instances in which we employed hyoscine in such a case the nervous excitement of the patient amounted almost to mania, and created so much alarm among his friends that the physician was at once sent for and implored by both the patient and the friends never to administer such a remedy again.

### SHALL ANÆSTHETICS BE GIVEN TO THOSE SUFFERING FROM HEART-DISEASE?

OUR attention has been called to this important subject by a brief article in the *New York Medical Journal* of October 14, 1893, in which Dr. Giffen, of Nebraska, concludes that the presence of valvular cardiac disease does not contraindicate the employment of these substances. We are firmly convinced that not only does valvular disease not contraindicate the use of anæsthetics, but, on the other hand, there is even greater reason for their employment in persons so afflicted than in those who are in ordinary health. The shock of the operation and the struggling from pain are both of them factors which will more seriously affect the heart than will any anæsthetics if cautiously administered, and those who have had the most experience as anæsthetizers are able to recall

many instances in which patients with heart-disease have taken the anæsthetic quite as well as those who have not had this trouble. Even if a valvular disease is associated with well-marked atheromatous changes in the blood-vessels and corresponding cirrhotic processes in the kidney, we believe that anæsthetics are preferable to no anæsthesia when operations are necessary. While it is true that ether, at least, distinctly increases cardiac action and arterial pressure, this increase is rarely sufficient in degree to do any harm. Chloroform is probably, in most of these instances, the safer anæsthetic in one respect,—namely, that it rarely produces the early stages of struggling which are often so characteristic of ether; but, on the other hand, any suspicion of fatty or other degeneration of the heart-muscle should force us to the employment of ether rather than chloroform. Auscultation of the heart will generally give us some indication as to the character of these cases. It will indicate whether the patient has accompanying his valvular lesion marked cardiac dilatation and enfeeblement of the heart-muscle. A therapeutic point to be remembered is not that the loudness of the murmur contraindicates the employment of an anæsthetic; it is the condition of the heart-muscle which must be taken into consideration. If the apex-beat is almost indistinguishable and the second sound muffled and feeble, if percussion indicates that marked dilatation is present, even if the murmur is heard with difficulty, we believe that the contraindication to the anæsthetic is very positive,—so positive that it should not be administered nor the operation undertaken without the physician impressing upon the patient and his friends that grave danger exists. On the other hand, the evidence of cardiac hypertrophy, as shown in the forcible impulse of the heart against the chest wall and the sharp sounds of the aortic valves, will indicate that anæsthetics can be given almost with the safety which is present when healthy men are anæsthetized.

#### POISONING WITH BISMUTH.

MANY years ago bismuth was supposed to be a poisonous substance; later researches proved that the toxic symptoms induced by its too frequent use were due to the presence of contaminating arsenic. A change in the source of supply of most of the bismuth of commerce, this new source not being contaminated with arsenic, soon proved that this last supposition was correct. Again, a few years

ago some French investigators proved that, when taken in very large doses for long periods of time, or when applied as a dressing to a large denuded surface, chronic bismuth-poisoning supervened, black gangrenous sloughs forming in the intestine and general evidences of cachexia developing. In view of these partly contradictory facts, the case reported in the correspondence columns of the *New York Medical Journal* of January 20, 1894, by N. L. Wilson, is of value.

A German girl, aged fifteen years, of nervous temperament, received a burn of the third degree on her back, covering an area of sixteen by fifteen inches. Nearly two months after the accident she was admitted to the hospital. During that time no history as to her treatment is available. On admission, the burned surface was scraped under anæsthesia, cleansed with a 1 to 3000 bichloride solution, and dressed with Squibb's subnitrate of bismuth. The dressing was applied every second day. At the end of eight days a black line along the margin of the gums of both jaws, headache, nausea, vomiting, paleness of the countenance, elevated temperature, rapid pulse, and an odor of urine on the breath asserted themselves. The urine contained a small amount of albumin. There was cedema of the lower extremities and marked diarrhoea, which continued until her death, which occurred eight days later. Tests made for lead and arsenic as contaminating substances in the bismuth gave negative results.

We therefore have a practical illustration of the correctness of Villejean's observations upon the lower animals when bismuth was used for a dressing, and the interesting clinical point is established that this substance possesses toxic powers in man as well as in the lower animals.

#### PEROXIDE OF HYDROGEN IN THE TREATMENT OF CONJUNCTIVITIS.

AT this season of the year numerous cases of acute catarrhal conjunctivitis distinctly contagious in character and sometimes giving the impression of an epidemic influence manifest themselves. Practically a self-limited disease, usually disappearing under moderate applications of astringent substances and irrigation with mild antiseptic lotions, typified by a saturated solution of boracic acid, this inflammation occasionally assumes a subacute character, and persists in spite of the ordinary methods of treatment.

At all times conjunctivitis, which appears in

manifold ways, may become an exceedingly troublesome affection, often recurring or relapsing with singular persistency. Sometimes such relapses are due to constitutional disturbances, sometimes to improper use of the eyes, especially under the influence of the strain of uncorrected ametropia, sometimes to associated naso-pharyngeal conditions, sometimes to occupations exposing the patient to irritating vapors, but very often because some of the layers of the inflamed conjunctiva have not been quite freed from the primary inflammation, exactly as the remnant of an iritis in the form of a synechia may occasion a relapse in an eye which otherwise has assumed nearly normal characteristics.

Now, the failure entirely to rid the numerous folds of the conjunctiva from the influence of that form of inflammation to which the general term conjunctivitis is given depends, in most instances, upon failure to properly cleanse the surface and prepare it for the curative applications. Very few, unless specially engaged in ophthalmic work, appreciate how large a surface the conjunctiva possesses, folded, as it is, on the under surface of both lids, and turning upon itself deep down in the upper and lower sulci, to be reflected upon the globe. Probably any of the well-known lotions would be effectual in performing this cleansing process, provided definite exposure is attained. One substance has in the hands of some surgeons seemed to fulfil this indication in a singularly happy manner,—namely, the peroxide of hydrogen,—which seems to have the faculty of penetrating the crevices readily and flushing out in a most effectual manner all of the little grooves in the much-folded membrane.

Originally recommended by Landolt in serious types of conjunctivitis, not now under consideration,—for example, those of gonorrhœal origin,—it has from time to time been re-advised, and is, no doubt, still the chosen lotion in the hands of numerous surgeons. Quite recently this drug has received the hearty commendation of Lautenbach in a paper before the County Medical Society of Philadelphia on "The Treatment of Various Forms of Conjunctivitis." Starting out with the important proposition that the treatment of all cases of conjunctivitis must begin by the cleansing of the conjunctiva, not simply its ocular or palpebral portion, but the whole of the membrane, including the folds, and that this necessity exists with acute as well as with chronic cases, he believes, on the basis of nearly ten years' experience, that peroxide of hydrogen fulfils more

effectually than other drugs this important indication. His method is as follows:

From 10 to 30 drops of the solution, which he uses in full strength, should be instilled at the outer canthus of the eye, and with the fingers a degree of massage applied over the entire surface of both eyelids. Then the eye should be looked at, and, if necessary, a second, a third, or even a fourth application should be made. In trachomatous cases it is advised that after the application the lid should be everted and its surface rubbed with the rubber end of an eye-dropper. After the application of the peroxide, the conjunctival cul-de-sac should be thoroughly irrigated with a saturated solution of boracic acid for the purpose of washing out the *débris* and soothing the irritation which follows the application. This treatment is never intrusted to the patient, but performed by the surgeon himself, once or twice a day, or perhaps only a few times a week, according to the indications. Very occasionally he prescribes for home use a weaker solution of the peroxide, to be used once or twice a day, the strength not to exceed a three- to eight-volume solution. Having thus thoroughly cleansed the inflamed surfaces, they are in a condition to receive whatever application is necessary to secure healing, be this astringent or cauterant, according to the exigencies of each case.

Dr. Lautenbach is fully aware of the fact that peroxide of hydrogen used in this way produces much smarting, and, if an improper preparation is employed, is capable of occasioning violent pain and even interfering with the nutrition of the cornea. Therefore certain requisites are needed before this somewhat heroic detergent application is suitable,—namely, that the peroxide should test beyond ten volumes, that it should not lose its oxygen on slight changes of temperature, and, most important of all, that little or no free acid should be present, only such amount being permissible as is consistent with the stability of the preparation.

Dr. Lautenbach's observations are interesting because his experience with peroxide of hydrogen is much more favorable than that which has come to many who have attempted to employ this drug for similar purposes. No doubt his explanation is the correct one, and that where great and serious irritation has followed its use, as has happened not infrequently to the writer of this article, undue amounts of free acid have been the cause of the untoward effects. The uncertainty of always obtaining a preparation fit for such cleansing purposes has led to a method already referred to in these

columns,—namely, the complete eversion of both lids and the thorough exposure of the inflamed conjunctiva, which is then cleansed by means of a spray of warmed boracic-acid solution, to which a few grains of common salt have been added, this spray being generated with the aid of an ordinary air-condensing apparatus, the pressure of which is so regulated that no tearing of the mucous membrane is possible, and yet all crevices and folds are sought out and receive the finely separated particles of the liquid.

Too much attention cannot be directed to the important practical point of Lautenbach's communication,—namely, the thoroughness of the exposure of the conjunctiva, and, as already pointed out, failure to effect this means in many instances failure to cure the affection under treatment. We are not prepared to endorse full-strength solutions of peroxide of hydrogen, but neither are we prepared to condemn them, because, in the light of the experience just related, care in the selection of the proper solution may obviate the difficulties which have heretofore seemed to make it an objectionable preparation.

#### *TREATMENT OF SWEATING FEET.*

THAT excessive sweating of the feet is to some extent a neurosis cannot be doubted, since the dependence of the condition upon innervation is shown by many phenomena, such, for instance, as unilateral sweating. The paresis of the nerves in the case of sweating of the soles and palms is probably peripheral and dependent upon either alterations of cold and heat, or, in accordance with more modern therapeutics, is associated in some way with increased thickness of the epithelial or horny layer of the skin, since removal of this horny layer is frequently followed by a radical cure. When the feet are affected, the sweating is confined to the soles and to the skin covering the plantar and lateral aspects of the toes. It begins towards the posterior plantar surface of the heel, usually of both sides at about the same time. The patch formed is rather clearly circumscribed, and presents a sodden, grayish-red appearance while the shoes and stockings are worn, but after the feet have been bare, as after a night's rest, appears glazed and reddish; it spreads over the entire sole, and is often distinctly inflammatory in type, making the feet so sore and tender that walking is painful. The affection is rendered still more distressing from the fact that it is often accompanied by a most offensive and penetrating odor.

The cleanliness of the foot-clothing is of course a matter of prime importance. Soft woollen stockings are usually considered best, and shoes of thin leather, which allow of some evaporation.

Hebra, in the treatment of this affection, has been particularly successful. He makes an ointment by melting diachylon plaster over a gentle fire and adding an equal weight of linseed oil, stirring well.

The foot, after being carefully washed and dried, has inserted between the toes pieces of lint covered with the ointment, and is then wrapped in a piece of linen spread with the same preparation.

Stockings and thin, low shoes are then put on. The dressing is repeated twice daily, the foot being thoroughly wiped each time. In a few days there is an exfoliation from the affected regions of a thick layer of cuticle, leaving a healthy skin below. After this has come away, astringent, drying dusting powders are continued for some days or weeks. The cure is generally accomplished in less than a month, and even should there be a relapse, this yields readily to repeated treatment.

During the last ten years the following methods, either single or combined, have been those of preference: Efforts towards lessening the sweat secretion by so arranging the footwear that rapid evaporation is provided for; the application of chemically drying materials; the thorough removal of the horny layer on the sole of the foot by Hebra's method, or by certain antihydroic solutions.

The management of the footwear should receive the most minute attention. It is of cardinal importance that shoes should fit properly and should not make pressure sufficient to interfere with the circulation. The upper of the shoe should preferably be made of some woollen stuff rather than leather, and low shoes are particularly commended for women. Gum shoes are especially to be avoided. Singularly enough, Jäger highly commends patent-leather shoes, though every one who has worn them well knows that to a limited extent they produce very much the effect of gum shoes. Cork soles, double stockings, and all other means of adding warmth to the feet are strongly condemned by Neebe. The fact that perfectly comfortable shoes will not necessarily relieve this affection is shown by the statistics of the German soldiers, sixty-seven per cent. of whom suffer from sweating feet.

The chemically drying materials have received the warmest commendations from all those who have practically tried them. Among

these the most valuable are combinations of alcohol with tannin or naphthalin; or powders, among the best of which are salicyl talc, salicyl-tannin starch, powdered tartaric acid, and, by no means of least importance, sulphur; or solutions, such as five- to ten-per-cent. chromic-acid lotion, or chloride of iron with glycerin.

The popular method of the day is, perhaps, the local application of a five-per-cent. solution of chromic acid, followed by the compound talc powder. Powdered tartaric acid is useless.

These methods, however, have never been entirely satisfactory. They improve the condition, but do not cure it. Hebra's method made a new departure in the therapeutics of this affection, but it requires too much attention to detail, is slow, and often fails.

Neebe therefore made an effort by means of hydrochloric acid to accomplish the same result, and after fifteen years of faithful trial with the raw acid, finds this agent entirely satisfactory.

The method of application should be followed closely. When the feet are galled or very tender, especially in hot weather, treatment is preceded by an eight- to ten-days' application of salicyl talc or compound talc powder, which is sprinkled in the stockings. The application of the acid is best made in the evening. The crude hydrochloric acid is poured into a flat vessel of stone or glass or porcelain, sufficiently large to receive the two feet. Since the soles of the feet and the skin between the toes are the seat of the trouble, sufficient hydrochloric acid is poured in this vessel to completely cover the soles. It should not be allowed to come in contact with the skin of the back of the feet. The heel is kept in the solution for five minutes; then the sole of the foot for ten minutes. After this the feet, especially the skin between the toes, are washed in soap and warm water. Soaking in the acid must be at once stopped as soon as pain is excited, and the painful spots must be coated with ointment until healing is complete. The crude acid gives rise to extremely pungent vapors, which irritate the throat. These may be avoided by breathing through a wet sponge or towel.

Applications are repeated twice weekly and continued for five to eight weeks. Patients usually express the fear that this raw acid is much too strong. This, however, is not the case, although, if the patients are extremely nervous, they may be allowed to add twenty-five per cent. of water, but after the first application to continue with the crude acid. The

author holds that with a quart of hydrochloric acid every physician is in a position to cure even the most obstinate case of sweating feet. Should there be a recurrence, cure is even more rapidly accomplished than in the first case.

Patients who will not consent to this treatment may be treated as follows: Every morning the soles of the feet and the skin between the toes is painted with a ten-per-cent. solution of nitrate of silver. This is continued until the whole horny layer on the soles and between the toes exfoliates. After one complete exfoliation, taking from eight to fourteen days, the remedy is applied only occasionally. This treatment is better than that with chromic acid. Practically, any method which accomplishes a thorough exfoliation of the superficial skin layers of the sole will give satisfactory results. It is important to note that cure of this affection is not only desirable because of the inconvenience it causes, but because it is a frequent cause of congestion of the mucous membranes, particularly those of the respiratory tract. Thus, many cases are recorded in which with the cure of the sweating feet the chronic catarrhal troubles from which the patients previously suffered disappeared. Even chronic catarrh of the stomach has been cured by this means.

## Reports on Therapeutic Progress.

---

### THE TREATMENT OF DIPHTHERIA.

*Apropos* of the recent publications of Escherich upon the local treatment of diphtheria by corrosive sublimate, A. DAMIANO (*Archiv. Ital. di Laringologia; Rev. Internat. de Bibliograph. Médicale*) calls attention to the practice of his teacher, Massei, who, in 1875, recommended spraying of solutions of bichloride of mercury (1 to 1000) in the treatment of diphtheritic angina. The recent bacteriological researches on the subject appear to sustain this practice, proving that the bacilli of diphtheria may be destroyed by corrosive sublimate in the strength mentioned. Experience seems to show that no danger need be feared from the employment of this method. At each spraying a larger quantity than 6 cubic centimetres should not be used. If the treatment is applied eight times in the twenty-four hours, the total dose of the medicament employed will not go beyond 5 centigrammes of the bichloride. The child, therefore, will never swallow more than a very minute quantity.

*THE PHYSIOLOGICAL ACTIONS OF THE  
SUBSTITUTION PRODUCTS OF  
GUAIACOL.*

According to the studies of PIO MARFORI (*Archiv. de Pharmacol. e Therap.; Rev. International. de Bibliograph. Médicale*), the general action of the monatomic compound radicals is that of *paralysis* after a short period of excitation. The toxicity diminishes from methylguaiaicol to ethylguaiaicol, and to allylguaiaicol, which is but slightly active. No convulsions are produced, as in the case of guaiaicol itself, which contains one hydroxyl, and particularly with pyrocatechin, which contains two hydroxyls. There is, therefore, a gradual transformation in the action of these substances by the substitution of the alcohol radicals for the hydroxyls, to which may be attributed the convulsant properties. The ethyl group gives to ethylguaiaicol its hypnotic properties. All these derivatives, in doses of .25 gramme per kilogramme of the body-weight, produce a slight reduction of the temperature. With the same dose, guaiaicol itself, and especially pyrocatechin, act very decidedly. In regard to the arterial pressure, the results obtained may be explained by the hypothesis that an hydroxyl imparts to the molecule the property of diminishing the pressure (pyrocatechin), the methyl ( $\text{CH}_3$ ) that of elevating it (methylguaiaicol). The other two alcohol groups, indifferent in themselves, influence the arterial pressure when they take the place of the action of the hydroxyl. Methylguaiaicol (or veratrol) is changed in the organism, in great part into guaiaicol, and is eliminated through the urine in the form of guaiaicol-sulphuric ether; a small portion passes unaltered through the kidneys. Ethylguaiaicol is also eliminated as guaiaicol-sulphuric ether. Allylguaiaicol is not much changed, and is found as such in the urine. The general action of the biatomic radicals is that of paralysis. The methyleneguaiaicol and the ethyleneguaiaicol are less poisonous than trimethylene- and propyleneguaiaicol. Benzoylguaiaicol, which belongs to the aromatic series, is transformed in the organism, partly into guaiaicol, which passes into the urine in the form of guaiaicol-sulphuric ether. Being inodorous, insipid, and non-caustic, it may be recommended as a substitute for guaiaicol itself.

*THE DYNAMOGENIC EFFECTS OF  
BLOOD-SERUM.*

A. CORIVEAUD (*Journ. de Médecine de Bordeaux*) details three interesting cases in which

the injections of blood-serum from the dog gave excellent results. The cases were, respectively, a rebellious anæmia, a chronic bronchitis with congestion of the base of the right lung, and a chlorosis due to mitral disease, accompanied with the most serious symptoms, such as vertigo, lypothemia, etc. All these cases made a complete recovery, and the author believes that there is no doubt as to the dynamogenic power of blood-serum. The injections appear to have the disadvantage of producing certain untoward effects, especially urticaria. The author believes that the method should be employed not as the primary treatment, but as a last resort in certain cases of profound anæmia, of prolonged convalescence, of phthisis, of neurasthenia with loss of power, —in all those cases, in fact, in which it is the main endeavor to infuse new energy into the organism. The injections of blood-serum should be practised preferably, according to the author, in the post-trochanteric region, by means of a long needle, being careful to deposit the liquid in the subcutaneous cellular tissue. Antiseptic precautions should in all cases be strictly observed.

*THE ANTIPYRETIC ACTION OF GUAIACOL.*

It has been held by several observers, particularly by Bard (see the reports on the subject in previous numbers of the *GAZETTE* during 1893), that guaiaicol locally applied diminishes the temperature mainly by being absorbed through the skin. How the drug acts to cause this remarkable reduction of the bodily temperature, when simply applied locally, has been studied in an interesting series of experiments by L. GUINARD (*Bulletin Générale de Thérapeutique*). The results of his experiments lead the author to conclude in general that the reduction of the temperature following the local application of guaiaicol, no matter to what region of the body it is so applied, is *not* the result of the absorption of the medicament through the skin. In many of the experiments performed, the rapidity with which the remedy acted tends to the support of this view. Experiments made on man and on the lower animals, especially the latter, by means of careful vivisections, demonstrate that guaiaicol acts upon the thermogenic centres through excitation of the peripheral nerve terminations, and reflexly upon the great functions.

The presence of guaiaicol in the urine of patients in whom the drug has been locally applied is due, the author believes, to the penetration of the vapors of the agent by the lungs,

because, when this way of entrance was avoided, no guaiacol was found three hours after a large application (10 grammes) of the drug. Again, the quantity of guaiacol taken in by the respiratory organs is not in itself sufficient to produce a fall of the temperature.

Regarding the local and general effects produced by guaiacol, these facts must be borne in mind: 1, the quality of the product used; 2, the individual susceptibility of the patient to whom it is applied; 3, the state of the general health. Guaiacol paintings, producing in febrile patients a marked reduction of the temperature, do not cause the same effects in apyretic subjects. However, even in the case of the latter, the action is manifest, especially when the guaiacol acts as an irritant, and when the individuals exhibit a special susceptibility of the skin, as happens in the case of the rabbit. The effects of guaiacol are more decided when the part upon which it is applied is covered over so that air is entirely excluded. The employment of guaiacol paintings constitutes an original, simple, and easy therapeutic measure which may render great services when the indications for their use are thoroughly established by further clinical trials.

#### GUAIACOL IN THE TREATMENT OF FACIAL ERYSIPELAS.

Continuing his clinical observations with the local use of guaiacol, L. BARD (*Lyon Médical*) details five cases of facial erysipelas treated by this novel method. From the results obtained he appears to be justified in affirming that the local application of guaiacol is efficient in the treatment of the disorder in question. The method results in diminishing the gravity and duration of the disease in a large number of cases. The author believes that this measure will also lessen the mortality of facial erysipelas. He advises the employment of 2 grammes of the drug for each application, this being made twice a day, provided the temperature is maintained below 39° C. The morning application may be dispensed with when the temperature does not go beyond 38.5° C.; that of the evening may be reduced to 1 gramme of the drug if the temperature does not go beyond 39° C. In order to avoid a too abrupt reduction of the temperature, as is apt to occur, it is better to use 1 gramme only at the first application of the medicament, without increasing this amount if the fever shows no tendency to ascend. [The results of this method have proved anything but useful in our hands.—ED.]

#### THE TREATMENT OF AN ATTACK OF GOUT.

*L'Union Médicale* gives the following advice in regard to the treatment of acute gout. Locally, it is best to apply to the inflamed joint, which, of course, is not to be moved, an ointment composed of—

R Hydrochlorate of cocaine, gr. iv;  
Vaseline, or almond oil, ℥iv.

Or to apply a bandage wet with—

R Menthol, gr. xv to xxx;  
Alcohol, ℥iij.

Or a lotion of—

R Menthol, ℥iv;  
Chloroform, ℥i.

Or iodoform collodion may be employed.

Internally, of course, colchicum is regarded as the best of remedies given, in the dose of 20 to 30 drops, or even a drachm of the wine of the root, care being taken that while the drug is pushed to its full physiological limit, the patient is not poisoned by it.

The salicylate of sodium is far inferior to colchicum in the treatment of this condition. In addition to this treatment for an acute attack, the following is employed as a prophylactic. It is advised that the bowels shall be actively moved every morning by one of the saline waters, chiefly those of the sulphate and chloride of sodium, and from 30 to 35 drops of the tincture of colchicum root, given once, twice, or thrice a day. If fever accompanies the attack, it is well to prescribe quinine in full doses, and if the pain is too excessive to be borne, morphine should be administered hypodermically.

In regard to dieting the patient, he should take as much as possible those waters which, while somewhat alkaline, do not necessarily purge, as, for example, those of Vals and Contrexéville, as they greatly increase the urinary flow and render the urine alkaline. Care should be taken, too, that the food does not consist of red meats and other gouty substances. Great fatigue should be avoided, as it tends to provoke another attack. Additional local treatment for an acute attack consists in local blood-letting, the application of iodine, of blisters in the neighborhood of the inflamed joints, of the employment of cold water locally and of antipyrin internally. Care should always be taken in prescribing colchicum to see that the kidneys are in a healthy condition, and should any irritative medicament be employed, this

precaution is to be followed. Should albuminuria indicate renal difficulty, an exclusively milk diet is to be recommended, and quinine is to be given internally in the dose of 3 grains morning and night. A saline purgative is to be used in the morning, and benzoate of sodium is to be given in the dose of 1 or 2 drachms every day.

#### THE USE OF PEROXIDE OF HYDROGEN AS A HÆMOSTATIC.

In the *New York Medical Journal*, Dr. BREWER recommends peroxide of hydrogen for the purpose of stopping hemorrhage. He has found it of great value in a number of cases. He states that it has been thought by some that the hæmostatic action of this drug is due in great measure to the fact that the peroxide-of-hydrogen fluid when brought into contact with organic matter is rapidly decomposed, giving off free nascent oxygen. This, by uniting with the hæmoglobin, converts the blood, which is generally venous in character and charged with carbon dioxide, into bright arterial blood, which, it is well known, is much more readily coagulable than the vitiated fluid.

Brewer was, however, led to question the correctness of this theory when he observed that in some of his most alarming cases the bleeding was distinctly arterial in character, and that these cases seemed to yield to the treatment as readily as those in which the oozing was undoubtedly venous.

Dr. W. G. Thompson placed the writer in possession of some facts which he observed during a series of experiments with this agent.

He observed that when a strong solution of peroxide of hydrogen (fifteen volumes or more) was brought into contact with the blood by being directly injected into the veins during life, it caused a rapid disintegration of the red corpuscles, resulting in the immediate precipitation of a semi-solid detritus which completely occluded the smaller vessels; that this effect extended so rapidly throughout the vascular system that within a comparatively short space of time the animal operated on would present the appearances characteristic of the most profound anæmia.

Thompson also observed that the application of strong solutions of this agent to mucous and serous membranes caused an almost immediate degeneration of the epithelial cells, resembling at first a rapid and exaggerated cloudy swelling, and later a complete destruction of the tissue.

In view of these facts, the writer is inclined to believe that the arrest of hemorrhage which

is observed when strong peroxide of hydrogen is applied to a freshly-wounded surface results from this remarkable disintegrating action both on the tissues and the blood, rather than the simple oxygenation and rapid coagulation of the latter, for it is easy to understand how the rapid swelling of the endothelial lining of the cut blood-vessels and the solidification of the blood would result in a more or less complete obliteration of their lumen.

#### THE TREATMENT OF ALBUMINURIC PHOSPHATURIA.

According to *La Tribune Médicale*, ROBIN read a paper on this subject before the Academy of Paris, December 19. He insists on the following treatment, which is largely hygienic and alimentary. The object of the physician must be to limit the disintegration of tissues rich in phosphorus, to favor the assimilation of phosphorus by the body, and to increase oxidation by the administration of such remedies as cod-liver oil, arsenate of sodium, and the phosphates combined with strychnine, quinine, or extract of cinchona; and, finally, by inhalations of oxygen. The physician must endeavor to increase the number of the red corpuscles, and to this end iron and strychnine are particularly valuable. For the albuminuria, gallic acid, pharmaceutical preparations of iodine, and a milk diet are to be resorted to. In addition, it is advisable in many cases to resort to mineral waters containing chloride of sodium.

#### THE TREATMENT OF DIPHTHERIA.

In the *Journal de Médecine de Bordeaux* a symposium as to the best treatment of this dangerous disease is given.

ARNOZAN considers diphtheria as a local affection, producing infection by the absorption of poisons formed in the false membranes, and that the treatment of the condition centres itself about three points.

1. Swabbing the affected parts by means of an applicator which has been wet with one of the following solutions:

Carbolic acid, 1 part;  
Glycerin, 20 parts.

Or,

Carbolic acid, ʒii.;  
Sulphuricinate of sodium, ʒii.

This application is to be made without violence, and should be resorted to every three hours day and night.

2. Frequent garglings or washings of the

mouth with boric acid or a feeble solution of carbolic acid.

3. The atomization or volatilization of carbolic acid in the air of the room, chiefly by means of evaporating a two-per-cent. solution of carbolic acid over an alcohol-lamp. Should the false membrane of the disease extend to the nasal fossæ or the larynx, this volatilization of the carbolic acid is to be directed towards the patient five or six times at night and ten or twelve times during the day. If the child is very young, it is best to employ boric-acid solutions as a mouth-wash rather than carbolic acid.

The general systemic treatment consists in the administration of the sulphate of quinine, alcohol, coffee, beef-juice, bouillon, broths, milk, and general alimentary tonics and digestives. The greatest importance is attached to proper feeding, and where absolute anorexia exists and food is refused, nutrition must be preserved by rectal injection.

DR. CHABRELY also summarizes his treatment under three headings:

1. The constant vaporization in the air of the room of phenated water, ten per cent.

2. Swabbing out the throat every two hours with lemon-juice.

3. The internal administration of chlorate of potassium and its use in gargles. [We believe that the internal use of chlorate of potassium in diphtheria is not only harmful, but distinctly dangerous.—ED.]

DR. LICHTWITZ recommends very highly the application to the diseased area of a solution of bichloride of mercury in distilled water in the strength of 1 to 500 to 1 to 100, and a gargle consisting of chloroform, 15 minims; distilled water, 4 ounces.

DR. MOURE also appreciates the necessity of strengthening the patient, and resorts to the following local treatment: As far as possible the patient should breathe an atmosphere which is well moistened. The bronchitis tents which are used so extensively in England he believes to be very valuable, and he also thinks that the vaporization of oil of turpentine is of service.

In regard to local applications, he believes that grattage of the tonsils and pharyngeal wall is of value, and applies the following solution afterwards:

R Antipyrin,  $\mathfrak{z}$ ii;  
Lactic acid, gr. xxx;  
Pure glycerin,  $\mathfrak{z}$ i.

Or, equally advantageously,

R Pure carbolic acid, gr. vii;  
Lactic acid, gr. xxx;  
Neutral glycerin,  $\mathfrak{z}$ vi.

He does not believe in violent applications to the area of false membrane, as this favors the extension of the disease. The applications of this to the throat should be made once or twice a day. If the child is old enough, gargles of alkaline solutions, such as bicarbonate of sodium or borax, should be resorted to.

DR. NEGRE recommends the following treatment: He applies to the part which is affected, by means of antiseptic cotton, lemon-juice every two hours, five or six times in the twenty-four hours. He employs a spray of solution of boric acid to the pharyngeal walls and nasal fossa, and gives tonic stimulant treatment. Should the case be very grave and the swelling of the cervical glands be considerable, he recommends as follows: Every two hours apply the following solution to the diseased area:

R Glycerin,  $\mathfrak{z}$ i;  
Carbolic acid,  $\mathfrak{m}$ xxv.

In these cases, too, he thinks that the following solution for the atomization of the nose and throat is of service:

R Carbolic acid, gr. lxxv;  
Distilled or boiled water, Oi;  
Glycerin,  $\mathfrak{z}$ iss.

He also thinks it of value to vaporize a twenty-per-cent. solution of carbolic acid in water in the sick-room, and to maintain a temperature of about 70° to 75° F. of the air of the room. Internally, he administers full doses of the chlorate of potassium with tonics, such as cinchona and alcoholic derivatives, in proportion to the age of the patients. Nourishment is to be pushed to the greatest possible extent.

DR. SAINT-PHILIPPE believes that we should remove the membrane, practise careful antiseptics of the pharynx, and sustain the vital forces of the patient against the intoxication resulting from the infective process, which is only secondary to the obstruction to the respiration produced by the membrane.

In regard to local treatment, he places his patient in a well-ventilated room at a temperature of about 70° F., and has constantly vaporized in the air of the room antiseptic substances, by preference carbolic acid or eucalyptus. He believes that cauterization of the diseased area is both barbarous and dangerous, and prefers antiseptic local applications, one of the best of which is lemon-juice, an advantage of which is that its application is devoid of pain. Tincture

of the chloride of iron is very active. A very favorite preparation with him is the sulphorinate of sodium and carbolic acid, as recommended by Arnozan in the beginning of this article. Some cases seem to be benefited by applying a powder of alum, tannin, and salol to the mucous membrane which is diseased. He regards washing the pharynx as an indispensable part of the treatment, which, of course, is not resorted to in young children, but even in them irrigation of the nose and throat should be practised. A useful application under these circumstances is lime-water. Where the temperature is high and the swelling of the neck is marked, ice applied to the swollen area and followed by a resolvent ointment, is of value.

DR. VERGELEY also places the child in an airy room, preferably upon a small iron bed, which is deprived of all canopies and similar clothing. He next insists that two persons capable of carrying out his directions to the letter shall take charge. Two or three times a day he applies to the tonsils and to the palate and pharynx, by means of a flexible applicator, a solution of boric acid, and follows it by a solution consisting of—

R Perchloride of iron,  $\mathfrak{z}$ i;  
Citric acid, gr. vii;  
Distilled water,  $\mathfrak{z}$ x.

In some cases, if the child is old enough, it may be well to insufflate a powder, consisting of—

R Boric acid,  $\mathfrak{z}$ i;  
Salol, gr. xlv;

which must be exceedingly finely pulverized before it is used. Every three hours he believes that the pharynx and tonsils should be irrigated by the following solution :

Distilled boiled water, Oi;  
Salicylic acid, gr. vii;  
Borax,  $\mathfrak{z}$ iss.

Internally, for the relief of pain and quieting the patient, as well as for influencing the disease, he recommends simple syrup, which should contain small doses of—

R Codeine, gr. vii;  
Chlorate of sodium,  
Flowers of sulphur, of each, gr.  $\mathfrak{x}$ .

If the patient is very much excited, it is well to replace the chlorate of sodium by the bromide of potassium. If diarrhoea comes on, a simple astringent mixture may be given, such

as wine of opium with a little syrup. If the false membrane is persistently reformed, it is well to employ an application of the perchloride of iron, or in its place an application consisting of—

R Glycerin,  $\mathfrak{z}$ iss;  
Metallic iodine, gr. iss;  
Iodide of potassium, gr. vii.

Sometimes, in place of this irrigation of the area, solution of sodium every six or eight hours is advisable until the false membrane disappears. It is also well to vaporize in the atmosphere, which should be diluted with water,—

R Powdered glycerin,  $\mathfrak{z}$ i;  
Crystalline carbolic acid, gr. vii.

During convalescence, quinine, iron, and salt baths, with frictions of the skin, are to be resorted to. Care should be taken that all discharges from the patient's mouth are thoroughly disinfected.

#### THE TREATMENT OF WHOOPING-COUGH BY BROMOFORM.

According to the *Revue Internationale de Bibliographie Médicale*, PELICER has employed bromoform with very good results in the treatment of this obstinate affection. It is a colorless liquid, produced by the action of bromine on alcohol in the presence of a base. When administered to animals by inhalation or hypodermic injection, it produces narcosis, without greatly disturbing the respiration or circulation. The dose is 1 drop for each year of the patient, given four times a day, but this dose should be increased progressively until it is taken many times a day. He has given as much as 48 drops a day during six days to a child of two years, but after this dosage he observed a general erythema, but no diarrhoea. There was increased frequency of the pulse and respiration. Bromoform diminishes the number of the attacks and their duration. Under its influence the vomiting ceases and the appetite returns. It is to be employed during a period of two or three weeks. In a number of cases he used it even longer than this.

#### THE USE OF OXALIC ACID AS AN EMMENAGOGUE.

In the *Medical News*, TALLEY records his experience with this substance. During the past twelve months he has used it with very

gratifying results in a series of cases of amenorrhœa presenting themselves for treatment at the Polyclinic and at the Pennsylvania Hospital. Talley does not entirely agree with Dr. Bloom in his article in the *Medical News* of October 14, 1893. While an efficient emmenagogue and a capable abortifacient, oxalic acid is not to be regarded as a perfectly safe drug. Within the last month he met with a case in which toxic symptoms followed the ingestion of three doses of  $\frac{1}{2}$  grain each, repeated at about four-hour intervals. The patient was an anæmic girl, twenty-two years of age, who gave a history of scanty menstruation and a complete cessation of her periods for three months. The uterus was not enlarged, nor were there any of the signs of pregnancy. She was placed upon oxalic acid in  $\frac{1}{2}$ -grain doses, which she was directed to take after meals, largely diluted with water. After the third dose she was seized with vomiting, pain in the epigastrium, and became completely prostrated. The pulse was weak and rapid and the extremities cold. She was placed in bed, external heat was applied, and the symptoms of collapse were soon overcome. She then complained of cramp-like pain in the hypogastrium and back. These symptoms were followed by an eruption upon the arms, trunk, and legs, resembling that of hives, which was still present seven days later and was attended with considerable itching. The symptoms gradually diminished in severity, the gastric symptoms being the most pronounced.

The action of oxalic acid seems to be directly as a stimulant to the uterine mucous membrane. It is, therefore, applicable to the treatment of amenorrhœa of the anæmic as well as of the plethoric type. Upon the pregnant uterus oxalic acid is capable of producing powerful uterine contractions, which terminate in the expulsion of the product of conception. This was observed in two cases of early physiologic amenorrhœa to which oxalic acid had been administered, the diagnosis of pregnancy not having been made.

Considering the fact, therefore, that oxalic acid, even when administered in fractional doses, is capable of producing toxic symptoms, and bearing in mind its powerful abortifacient properties, we should be guarded in recommending it as a safe remedy. Talley considers it a valuable drug in the treatment of amenorrhœa, but one that should be given guardedly, carefully watched, and only prescribed when the diagnosis of pregnancy has been excluded.

#### SALINE TRANSFUSION.

The somewhat sensational procedure of the transfusion of blood as a means of rescuing moribund patients from death from hemorrhage has been known and practised from time immemorial, though it cannot be said, outside of novels belonging to the melodramatic school, to have been productive of anything like uniformly satisfactory results. The fact is that blood is a very delicate fluid, and requires special skill and appliances for its transfusion, otherwise it may prove the means of precipitating the catastrophe which it is sought to avert. Of late years, especially since the regretted Dr. Woolridge devoted special attention to the physiology of the subject, the practice of injecting saline solutions directly into the veins has come more generally into vogue, with the happiest results. At first the endeavor was made to compound a solution of salts theoretically conforming to the blood plasma, but this has since been shown to be quite unnecessary; in fact, pure water at a suitable temperature may be injected with impunity in comparatively large quantities. In any event, it is sufficient for the purpose to measure roughly about a teaspoonful of common salt to the pint of boiled water, and cooled down to about 100° F., in preference, though even this precaution is not essential to success, provided that the actual temperature of the solution does not fall notably below blood-heat. At the last meeting of the Obstetrical Society, Dr. Horrocks was enabled to relate a series of cases in which patients, pulseless and apparently moribund from severe hemorrhage, were promptly and almost uniformly rescued from impending death by the free and immediate use of intravenous saline injections. Not the least remarkable fact about these cases was the quantity of fluid that was employed, amounting, as it did, in several instances, to upward of six pints. Moreover, the apparatus required for saline transfusion is of the simplest possible character, comprising, as it does, only a funnel or jug, some tubing, and canula for insertion into the vein. There is nothing in the proceeding to disturb the equanimity of even the most timid practitioner, and as the procedure is, we believe, destined to become more generally employed, not only in hospitals, but in private practice, its simplicity and the ease with which it can be carried out are very important features. It is not only in cases of severe hemorrhage that these transfusions are useful. They have been employed with strikingly good results in shock, and we have known surgeons to order copious injec-

tions prior to commencing an operation on patients whose condition was such as to inspire doubts as to their ability to resist the further shock of operation. We are not as yet in a position to dogmatize as to the ultimate value of injections against shock, but Dr. Horrocks's cases prove beyond the reach of doubt the extreme usefulness of this last means of averting death in a very common and 'tragical series of cases. Although Dr. Horrocks repudiates any knowledge of the value of the transfusion of saline solutions in shock pure and simple, it must be very difficult to distinguish between the collapse due to the hemorrhage and that attributed to the shock which is associated with loss of blood, even in relatively small quantities, so that it is quite possible that some of his cases were, after all, due to shock. The arguments on which the proceeding is justified are straightforward enough. The removal of a large quantity of blood determines such a lowering of the blood-pressure that the circulation falls through, so to speak, for want of a circulating medium, and this in spite of the fact that on physiological data we are warranted in assuming that what remains would be sufficient to carry on the vital processes if only it could be circulated. The introduction of a quantity of fluid roughly corresponding to the amount of blood lost, re-establishes the circulatory balance. It must, however, be had recourse to without loss of time, because the heart and arteries rapidly lose the power of propelling the blood once that function has fallen into abeyance. Altogether, the transfusion of saline solutions is a very valuable procedure, well within the reach of the every-day practitioner, requiring no special skill or apparatus to carry out. For this reason it is highly desirable to generalize a knowledge of its use, the more so seeing that in text-books transfusion of blood is still recommended as a *dernier ressort*, showing that their authors are still ignorant of this newer plan of obviating the immediate consequences of the direct abstraction of large quantities of blood.—*Medical Press and Circular*.

#### BROMIDE-OF-POTASSIUM-POISONING.

DR. GREENLESS (*Quarterly Journal of Intemperance*, vol. xvi., No. 1) has recently published several cases of poisoning from this source. The first case was an epileptic, who took 75 grains a day for three weeks, when stupor, coma, and extreme prostration and death followed. The post-mortem showed intense con-

gestion of the meninges. In another case, an epileptic, the same amount of bromide of potassium—75 grains a day—was given, and in ten days coma and death followed. Both the brain and meninges were congested and the kidneys were in the advanced stage of cirrhosis. The other cases were less prominent, and clearly from bromidism that was the result of long use of the drug. In some cases of inebriety larger doses of bromide produces stupor and prostration, from which recovery is slow, and followed by continued prostration. It is an error to suppose that the bromides are harmless. In certain cases they are capable of causing very serious results, and should be used only for a short time in large doses. We have yet to learn many things concerning this very commonly used drug.

#### NITRATE OF STRYCHNINE IN ALCOHOLISM.

From the results obtained in twenty-five cases we can learn that, simultaneously with the use of this remedy, the craving for alcohol in inebriates diminishes and in a few days is completely gone, and through the withdrawal of the poisonous beverages and the tonic effects of the strychnine there is a more or less rapid restoration to sound physical health and of the mental powers; but as most of those treated have relapsed within from one to eleven months, the inhibiting power of the remedy is not permanent, and while it temporarily relieves the distressing and overwhelming craving for more stimulant and promotes a return to normal health, in which condition the patients may continue to remain, yet they still lack the necessary will-power to enable them to avoid the dangers which they know will precipitate a return to their previous enslaved and degraded condition. So that, while it is fully within the power of medical science to restore these patients to temporary health, strychnine does not—as doubtless no drug treatment ever will—prevent the possibility of further relapses, although we can always depend on it to arrest what would be a prolonged debauch if its aid is early resorted to. That weakened will-power is a result of a prolonged use of alcohol is generally conceded, as is the fact that the tendency to alcoholism is in a large percentage of cases inherited, and it is often, as dipsomania, one of the manifestations of insanity; that a definite series of pathological conditions follows the continued indulgence in alcohol, differing only in degree in the case of the milder methyl to the powerful effects of amyl alcohol, the nervous system showing the

earliest and most marked disturbance, although every organ and tissue in the body eventually suffers. These and many other facts have led neurologists to place alcoholism as a distinct disease among the neuroses.

This position implies a complete revolution in the methods of treating these cases, and has brought to the aid of philanthropists and moralists the assistance of the medical profession, upon whom now devolves the duty of further elucidating the true pathology of the disease and indicating the best means of restoring this numerous class of patients to a normal condition.

That the urgent demand for relief from the evils of intemperance is being recognized by the profession is evidenced by the increased interest taken in the work of the American Association for the Study and Cure of Inebriety, and in the Section for the Study of Inebriety of the British Medical Association, and by an ever-increasing number of scientific investigators throughout the world.

Before rational and effective measures can be adopted for the proper management of inebriety, we must have correct opinions in regard to the physiological actions of alcohol and the pathology of the disease; otherwise we must trust to the empirical results of experience.

The chief action of alcohol, then, is to paralyze the vaso-motor system, dilating the arteries. Strychnine, besides exalting the excitability of the spinal cord and probably the motor centres in the brain, stimulates the vaso-motor centres, contracting the arterioles, as well as being one of the most efficient heart tonics through its stimulating effects on the cardiac ganglia.

While we have in strychnine a true antagonist to the action of alcohol and one that will counteract its effects, the inebriate still requires aid which can scarcely be expected of drugs; he needs the mental and will-power to overcome his acquired or inherited tendency to resort to narcotics. This must come from treatment which seeks first to restore all the abnormal conditions of the patient, whether due to alcohol or otherwise; then strict abstinence must be maintained, the patient being aided by moral suasion, the diversion of continual employment, and the education of the mental and moral faculties to a higher status; even the influence of hypnotic suggestion may be applied in suitable cases, as has been done recently with a fair measure of success; and, where these means fail, then institutions where voluntary or forced detention can be secured,

and where all the present known means can be most successfully applied, must be the only hope of restoring the unfortunate subjects of narcomania.

#### THE TREATMENT OF PNEUMONIA.

In the *Virginia Medical Monthly*, DR. CUNNINGHAM, of Ensley, Ala., contributes a very valuable paper upon this subject, regarding the results reached by him in the treatment of ninety-three cases of croupous pneumonia at one of the prison missions of Alabama. In the matter of treatment he discusses chiefly the use of stimulants, antipyretics, and special measures. In eight of his cases no stimulants were used. In the remaining eighty-five, whiskey was used in all, strychnine in forty-one, digitalis in fifteen, strophanthus in twenty-four, carbonate of ammonium in six, nitro-glycerin in two. Strychnine, which was employed pretty much through the entire attack, was aided in the event of extreme heart-failure by strophanthus, but in some cases it was found necessary to give  $\frac{1}{10}$  grain of the latter drug every three hours as a matter of routine. Under these circumstances it was always given hypodermically, and the effect produced by it was remarkable. The digitalis and carbonate of ammonium were abandoned as useless; particularly does Cunningham believe that carbonate of ammonium is of no value. The antipyretic measures which were employed were baths, quinine, phenacetin, and acetanilide. In eighty of the ninety-two cases in which antipyretics were used, twenty-eight died, but twenty-one of these suffered from a double pneumonia, which practically involved the entire pulmonary tissue on both sides, and would therefore probably have been fatal in any event. He reaches the interesting conclusion, from a careful analysis of the various cases, that the mortality in the bath cases was 1 to 2.25 of the other antipyretics. He therefore believes that the bath method of reducing the temperature in pneumonia is the safest that can be resorted to. Under special treatment, he confines his remarks chiefly to the employment of hypodermoklysis, or the subcutaneous injection of a saline solution, chloride of sodium, one drachm to the pint of water. This method of treatment he believes to be absolutely new in croupous pneumonia. He employs it with the object of producing reaction from the prostration and marked debility which are present in many cases, and he believes that its employment was followed by advantageous results, particularly in those cases

which were suffering from apparent cardiac failure, which, he thinks, may be due to ante-mortem heart-clot. He believes that the addition of chlorides to the blood, which are under these circumstances passed out of the body too freely, does much towards preventing the formation of clots in the cardiac cavity, and employs daily from 4 to 12 ounces in this way. Of course it is necessary that the salt solutions should be boiled and the operation performed in an absolutely aseptic manner. The conclusions which he reaches at the end of his valuable paper are as follows:

1. It is a constitutional disease with a local anatomical sign, consisting of an inflammation of the pulmonary parenchyma, and caused by its own specific materies morbi or germ, probably that of Fränkel or Friedländer.

2. That the special circumstances under which this germ is evolved and operates are unknown, as we have it under diametrically opposite conditions, both good and bad.

3. That the disease, as a rule, prevails endemically, rarely epidemically, and still more rarely sporadically.

4. That these endemics differ in type and in extent of pulmonary inflammation, and, consequently, in mortality.

5. That the disease is severer in public institutions, especially prisons.

6. That the negro is especially predisposed to the disease, has less capacity to resist it, and, consequently, a larger mortality.

7. That coal-miners, especially negroes, while not predisposed to the disease, are favorable subjects for extensive pulmonary inflammation, and have less capacity to resist the disease, owing to the more or less anthracosis of the pulmonary tissue.

8. That the mortality is mainly determined by the type of the disease; first, in the primary effect of the germ upon the nervous system; and, secondly, in the extent of pulmonary inflammation and in the rapidity of its invasion and development.

9. That the mild, uncomplicated cases, with a fairly good pulse and moderate temperature, and with only one lobe, especially a lower lobe, involved, intrinsically tend to recovery; and that the severe cases, complicated or not, with fast and weak pulse, fast or labored respiration, regardless of temperature and attended by great prostration, intrinsically tend towards death, and without judicious treatment will die, regardless of the extent of pulmonary inflammation; and that in the cases in which the pneumonia is double, particularly if the double invasion is simultaneous, their tending is to a

fatal issue; and, finally, that in the cases in which the inflammation is universal by a simultaneous or rapidly successive invasion of the entire lung structure, death is the inevitable rapid result. Therefore, in comparing statistics, all these things should be taken into account; otherwise they are worthless. Hence the wide divergence in the statistics and difference in treatment of various observers.

10. That the immediate cause of death in many cases is ante-mortem heart-clots.

11. That the main features of treatment are: (a) to combat the shock of the germ invasion, best done by opium, stimulants, and, in the writer's opinion, hypodermoclysis; (b) to stimulate freely, the best stimulants, as a matter of routine, being whiskey and strychnine, supplemented in extreme cases by tincture strophanthus; (c) to control temperature, the best method being the bath; (d) to prevent, if possible, heart-clots, hypodermoclysis, in his opinion, being the most reliable; (e) to meet indications as they arise.

#### *THE TREATMENT OF SEVERE ALBUMINURIA ASSOCIATED WITH PREGNANCY.*

In a paper read at the last meeting of the Obstetrical Society, Dr. HERMAN (*Medical Press and Circular*) concluded a valuable series of observations on albuminuria associated with pregnancy and labor. Every practitioner who observes his cases must have noticed that there are at least two main groups of kidney-disease in this association. Albuminuria in a more or less marked degree is a very common complication of pregnancy, but in a large proportion (the majority) of the cases it does not lead to any of the graver symptoms to which pregnant albuminuric women are liable. In a certain number of such patients, however, not only is the disease acute in its onset and violent in its manifestations, but we get the dreaded eclamptic convulsions which threaten the life of the mother and jeopardize that of the unborn infant. The risks dependent upon the renal disease are, then, first, the life of the mother; secondly, that of the foetus; and, lastly, the danger of the acute phase giving place to a chronic form of Bright's disease after delivery. The main points which still call for discussion are the means of distinguishing between the cases which are likely to import a grave sequel, and the best method of obviating the danger of usual defects and renal disease as a sequel. Dr. Herman tells us that the acute form attacks mainly women who are pregnant

for the first time, and he points out that when the albumin in the urine consists mostly of serum albumin the prognosis is grave. It is, therefore, necessary for the practitioner to accustom himself to testing for the presence of paraglobulin as compared with serum albumin. One of the common symptoms associated with the albuminuria of pregnant women, as in albuminuria from other causes, is failure of vision, attributable to the presence of albuminuric retinitis, and possibly subretinal hemorrhages. In the graver cases this may go on to complete loss of perception of light. Although in most cases the cecity passes off more or less when delivery has been safely accomplished, this is by no means always the case, and the preservation or protection of sight becomes one of the points to which treatment must be directed. Now, the treatment of the albuminuria of pregnant females is practically confined to the induction of premature labor. As soon as the uterus has been emptied, the symptoms usually promptly subside; indeed, the promptness of this subsidence is one of the most remarkable features of renal disease associated with pregnancy. The speakers in the discussion that followed accepted this conclusion, and did not hesitate to recommend that the uterus should be emptied forthwith in all really serious cases of albuminuria associated with pregnancy. The child is sacrificed, it is true, but its chances of survival in the presence of eclampsia, or even of severe albuminuria, are small indeed, so that this fact cannot and ought not to be allowed to weigh in the balance, especially as the mother is thereby rescued from one of the most terrible complications that can threaten the pregnant woman. Then, too, in the cases presenting indications of albuminuric retinitis. These are always severe cases, and most of them die if left unrelieved. Moreover, the further the case is allowed to go on the greater is the damage done to the delicate structures of the eye and the greater are the risks of permanent impairment of vision. This is a serious point well worthy consideration, and in future obstetricians will be well advised if they adopt the suggestion to empty the uterus as soon as, at latest, ophthalmoscopic examination reveals the familiar and easily-recognized signs of albuminuric retinitis. There remains as an additional reason for adopting this course the fact that, even in women who either do not have, or who survive, the fits, the kidneys do not always recover from the disturbance to which they have been subjected, and the patient not infrequently remains the victim of chronic Bright's disease.

On these grounds, therefore, severe albuminuria ought to be added to the list of indications for the induction of premature labor, without waiting for the supervention of eclamptic convulsions before coming to a decision. This is not a specialist's question. It is one which any practitioner may be called upon to consider at any moment, and it is to be hoped in the best interests of his patient that he will henceforth recognize the extreme and manifold gravity of the risks attending the continuance of albuminuria in pregnant women.

#### *THE TREATMENT OF SPASMODIC TORTICOLLIS BY CONIUM.*

Before the Section of the College of Physicians of Philadelphia, DR. SINKLER read a paper on this topic. He pointed out that drugs of all kinds have been recommended in the treatment of this affection. Splints and mechanical appliances are of no benefit, but usually aggravate the affection. From the fact that frequently the muscles principally involved are the sterno-mastoid and the trapezius, the affection has been supposed to be due to disease of the spinal accessory nerve, and treatment has been directed to this nerve.

Counter-irritation, galvanism, and actual cautery, applied as near as possible to the origin of the nerve, have been used, but with far from satisfactory results. Surgical measures, such as stretching this nerve and the excision of a large portion of it, have been resorted to, but in only a small proportion of cases has relief followed the operation. It is, therefore, evident that the disease, except in rare cases, involves the deeper muscles of the neck, as well as the sterno-mastoid and trapezius.

Lezynski recommends the use of belladonna, given in increasing doses almost to the point of toxic influence, and keeps this up for four or five weeks. He has had marked success from this method, and Grey says that since he has followed Lezynski's plan he has cured eight cases of spasmodic torticollis by the use of belladonna. Wharton has used this remedy also, but without success. The best results which he has seen from drugs in this disease have been from the use of conium. This drug was recommended by Harley many years ago in the treatment of spasmodic affections, but it never has been used extensively. G. M. Hammond reports the successful treatment of a case of painless facial spasm by the use of this drug, and Rockwell, of New York, recommended it in the treatment of chorea. The text-books, however, do not speak of it favorably. Hare,

in his work on "Therapeutics," remarks, "that conium holds an unimportant place in the drug-list of to-day." He has found, as in Sinkler's experience, however, that it is decidedly useful in many forms of muscular spasm, when not due to central causes.

From experiment it has been found that conium causes paralysis of the motor nerves when given in physiologic doses. There are drooping of the eyelids, staggering and inability to walk, showing its influence upon the muscular system. It is, therefore, reasonable to expect that in the treatment of muscular spasms, when peripheral in origin, the remedy would prove useful.

Harley recommended the juice of fresh leaves, but this is difficult to obtain, and the fluid extract is a reliable preparation. The dose in which it is recommended in the text-books is entirely too small to be efficacious. The writer usually begins with 15 or 20 drops three times a day, and frequently increases the dose to 60 drops. There are two fluid extracts in the market,—one of the leaves and the other of the seeds. Sinkler usually gives the latter. He has seen several cases of spasmodic torticollis which were relieved by this remedy, and two or three cases of painless facial spasm which were distinctly benefited by its use, in one of which the spasm entirely ceased.

#### POISONING BY CAMPHORATED OIL.

Among a number of reports of cases of poisoning by various substances in the *Pharmaceutical Journal and Transactions* is one detailing the case of a child aged five years. The mother stated that the child had been suffering from whooping-cough, and that she had been using camphorated oil over its chest and back. In attempting to give the child its medicine, she poured out by mistake a teaspoonful of camphorated oil and gave it to the child. The child at once complained of its taste, and the mother, who smelt the spoon, found out her mistake. The child died in epileptic convulsions, adding another case to the records which show that poisonous doses of camphor produce such convulsive disturbances.

#### A CASE OF STRAMONIUM INTOXICATION.

MAISCH, of New York, reports a case of this character in the *Medical Record* of October 21, 1893.

The rarity of these cases, at least in our

larger cities, and the marked manifestations exhibited in this instance, led the author to place the following on record:

Some three months ago he was summoned, early in the morning, to Mrs. B. The impression made upon the recorder was that he had to deal with a case of acute alcoholism. The patient, a woman about thirty years of age, well developed, robust, and healthy in appearance, retired perfectly well and sound one hour before, and fell asleep shortly after lying down. She had not been exposed to any contagion, "nor had she taken any stimulants or medicines." Shortly after falling asleep her husband noticed that she became very restless, "breathing deeply and loudly," and upon rousing her she appeared "out of her mind and wild." Pulse, 130 and thready; conjunctivæ deeply injected and reddened; eyes wildly staring and restless. Face and chest covered with an erythema like that of scarlatina or that caused by belladonna. Tongue and fauces dry and parched; respiration shallow and increased to 35 per minute. Wild and active delirium; hallucinations of sight and hearing. Complaints of intense thirst and severe frontal headache. Patient almost unmanageable, throwing and breaking everything within reach, and constantly looking under bed and searching closets for strange men and animals.

The symptoms were those of atropinismus, and, after administering copious draughts of warm water, salt, and mustard to gain time, the author gave sulphate of morphine in the dose of half a grain subcutaneously.

Upon declaring to her husband that the patient must have imbibed something that was poisonous, he learned from a servant that her mistress had taken some kind of tea before retiring.

Upon being shown what remained, the toothed, ovoid thorn-apple leaves, the bitter, pungent, and metallic taste peculiar to it was recognized.

On further search, a package of compressed stramonium leaves, such as is sold in the stores, was found. Diagnosis was established.

One hour after the exhibition of the morphine salt the patient was resting quietly; an ice-bag had been put to her head and morphine sulphate .015 (gr.  $\frac{1}{4}$ ) was ordered every four hours, and cold black coffee for the thirst, which still was intense. The next forenoon she had become perfectly rational; the erythema had disappeared, as had also the throat symptoms. She had not the least recollection of what had occurred during the night after having taken the tea, which was intended to rest

her menstrual flow. The mydriasis lasted for almost four days.

It may be of interest to know how much of the drug had been taken. The package contained one ounce of the dried leaves, of which one-half had been used in preparing the infusion; to this was added a cup (eight ounces) of boiling-water, and after standing one-half hour, she took two tablespoonfuls. From this we may deduce that one ounce of an infusion of the strength of 1 to 16, considerably weaker than is official (1 to 16), caused toxic effects in this case. The quantity is certainly not a large dose, and it is to be presumed that the woman has an idiosyncrasy for the drug. Patient made a complete recovery.

#### OLIVE OIL IN THE TREATMENT OF NEPHRITIC COLIC.

AUSSILLOUX (*Bull. Génér. de Thérapeutique*) reports two cases of nephritic colic, occurring in elderly persons, in which the administration of olive oil produced most excellent results. The action of the oil in controlling the crises of the disorder was undoubted. How the drug acts, whether directly upon the calculi themselves or owing to its cholagogue or purgative properties was not determined. The action is apparently a reflex one, though even this cannot be accurately demonstrated clinically or experimentally. The oil stops the spasms of the ureters, as does a hypodermic injection of morphine, with the important difference that in the case of the latter remedy the relief produced is only temporary, whereas in the case of the oil it is definite. The oil seems to act in nephritic colic precisely as it does in hepatic colic, about which many observations have already been published. Regarding the administration of the oil, some practitioners prefer to give it in single doses of from 150 to 400 grammes or more. The author, however, recommends small quantities at a time, repeated as required. He refers to a singular method of administering the medicament in certain parts of France,—that is, in garlic broth; this is prepared by boiling a few cloves of garlic in water with a little salt. The broth is then poured over slices of bread soaked in the oil, constituting in this manner garlic soup. The author leaves out the bread and increases the amount of the oil from two to four tablespoonfuls. Patients take this beverage more readily than the pure oil, and it has been found to be just as efficacious. The dose may be repeated in the course of a few hours, if necessary.

#### THE PHYSIOLOGICAL ACTION OF DUBOISINE.

DE MONTYEL, the chief physician of the insane asylums of the Seine, contributes a paper on this topic to *La Tribune Médicale*.

"The question is, Does this substance modify the secretions? It does in a marked manner. First, it has the incontestable property in every case of constantly drying the skin and mucous membrane. The drying of the skin causes no inconvenience, and the patients do not perceive it. It has not the same effect so far as concerns the drying of the buccal mucous membrane, which has never failed to cause great discomfort, all our cases, without exception, having complained of the dryness of the mouth. When I say all our patients, I am wrong, for two epileptics and two hysterical cases had abundant salivation, and the first two, moreover, had the body covered with perspiration. These anomalies, however, were due, I believe, not so much to the drug as to the idiosyncrasies of the patients, salivation forming part of their disease. The duboisine also has diminished the urinary secretions in some cases very notably. Thus, in thirty-seven cases—that is, fifty-four per cent.—the quantity in twenty-four hours was less than four thousand grains. These figures are all the more surprising, inasmuch as the majority of our patients were subject to polyuria; but duboisine differs markedly from thymacetine in that it has no influence on micturition.

"One patient, it is true, after a dose of 1 milligramme, had the first day a urethral spasm of short duration; this patient suffered from general paresis. There are two other effects of this drug, besides that upon the heart, which remain to be considered. The first is its action upon digestion. The effect upon stomach digestion has been injurious. However, this was not the case with intestinal digestion, except that it produced a slight degree of constipation, owing, perhaps, to the suppression of the intestinal secretion. This has not been found to be the case by other observers, and possibly these discrepancies are due to individual idiosyncrasies.

"With reference to its effect upon gastric digestion, our cases may be divided into three classes,—first, those who were simply the subject of experiment; second, those who were undergoing a sedative course of treatment; third, those who were treated for insomnia.

"The most decided symptoms were observed in cases of the second group,—those on sedative treatment.

"In the first days of the medication there were no marked symptoms, but on continuing it there were decided digestive disorders, which appeared at variable intervals, according to the dose and individual susceptibility.

"First there was a diminution of appetite, with or without a coated tongue and a perverted sense of taste. Some of them stated that their appetite was diminished and that they had a distaste for all nourishment, while others complained of a constant unpleasant taste in the mouth, resembling that of soap, which was imparted to their food. This gave rise to the suspicion that they were being poisoned.

"This perversion of the sense of taste was, however, rare, since among thirty-five cases it was only observed five times,—that is, thirteen per cent. A more frequent symptom was vomiting, which occurred in ten cases,—that is, in twenty-nine per cent. In three instances the vomiting was very slight. The vomiting occurred exclusively at mid-day or in the evening,—that is, at the principal meals or immediately after them. It appeared to be due to an intolerance of food. The patients had no sooner begun to eat than they rejected the few mouthfuls which they had swallowed, and then resumed their meal without apparent inconvenience. In no instance was the vomiting sufficient to empty the stomach completely.

"More rarely the vomiting occurred shortly after leaving the refectory, but still only partially emptied the stomach, as it was never continuous, several days sometimes passing without its recurrence.

"Among the twenty experimental cases of the first group gastric disorders were less pronounced. Not one of those who took the drug for the period of three days suffered from nausea. Only hysterical patients on the fifth and sixth day made attempts at vomiting, which were unsuccessful.

"These facts confirm the preceding statement that the stomach disorder is not an early effect of the drug. It must, however, be admitted that in forty-five per cent. of these cases there was loss of appetite, attributed by the patients themselves less to the remedy than to their confinement to bed.

"The importance of determining whether or not duboisine exerts an injurious effect upon alimentation, even when vomiting does not occur, will shortly be made manifest.

"The thirty-one insane of the third group, to whom duboisine was administered at bedtime, enjoyed an almost absolute immunity from gastric

disorders. These cases, in which we prescribed the remedy, we observed closely in regard to these symptoms. In only two cases—one an alcoholic, the other a paralytic—did vomiting occur. In a maniac's case complete loss of appetite was noticed. From the foregoing it appears that gastric disorders occurred in a descending scale in the three classes of cases,—slight in the first, very pronounced in the second, almost absent in the third. We believe the reason of these differences to be due to the mode of administering the remedy, or rather to the time of its administration, for the doses of the drug and the duration of its administration seem to count for nothing, as the doses were as great and the remedy was continued for as long a period in all the cases. On the other hand, the differences as to the time of the injections were very great. The patients to whom the drug was administered as a hypnotic dined at six o'clock and received their hypodermic injections at half-past seven,—that is to say, at the height of digestive activity,—and suffered no inconvenience. It appears, therefore, that duboisine does not exert an injurious action if administered while digestion is in progress, but if given in the intervals between meals it disorders the ensuing digestion.

"The insane to whom the drug was administered as a sedative, and who took their meals three hours after the injections, suffered from marked gastric disorders, while those who took the drug in the evening while digestion was in progress, and who passed the night without eating, receiving no food until the next day at seven o'clock,—that is, thirteen hours after the injection,—were, as previously stated, free from gastric disorders.

"It is, therefore, manifest that duboisine may be given without inconvenience or unpleasant results immediately after meals, provided there is a lapse of at least five or six hours before the next repast.

"Ignorant as we were at first of these facts, we made the mistake of selecting the hours of nine in the morning and three in the afternoon as the times for administering the drug.

"We are about to undertake a new series of experiments to ascertain whether the same patients who vomited under these conditions will be free from digestive disturbances if the injections be administered at seven in the evening and at noon immediately after the mid-day meal.

"It is of great importance to endeavor by all possible means to reduce to a minimum the action of the drug upon the stomach. If di-

gestive disorders were inseparable from its administration, we would be hardly able to avail ourselves of its admirable sedative properties.

"We will now consider the influence of duboisine upon nutrition. Judging from the thirty-one cases to whom the drug was administered during the day for the purpose of allaying nervous excitement, the effect was decidedly disastrous. These cases have all lost flesh, some of them to such an extent as to compel us to abandon the use of the drug.

"Not anticipating such a result, we omitted to weigh our patients at the beginning of the treatment, but did so as soon as it was abandoned on account of their emaciation. We then observed that, in spite of symptoms of nervous agitation, which had been partly suppressed by the drug, they rapidly gained in weight, some of them to the extent of six kilogrammes in three weeks. It is, therefore, incontestable that duboisine, in spite of its marked sedative effect, exerts an unfavorable influence upon nutrition.

"It must be observed that there were never any unpleasant local accidents at the points of the injections. A few of the patients complained bitterly of them and offered vigorous resistance, some without giving any reasons therefor, others complaining of severe pain; still others believed it to be a device of their enemies, while another set were unwilling to be the subjects of experiment; but in reality no local disorder was ever produced, although the general nutrition was injured.

"This fact being placed beyond question, we next proceeded to investigate as to whether these nutritive troubles were the direct result of the action of duboisine or an indirect consequence of the disorders produced in certain organic functions. Duboisine has the property of raising the temperature; in other words, of increasing combustion; at the same time it retards the circulation, besides causing a bitter taste in the mouth and anorexia. I was led to regard the emaciation which followed its use as the result of these altered physiological actions. However, further observation of the patients did not confirm the opinion, for many of them became so emaciated as to necessitate the withdrawal of the remedy, although they had never vomited and had never suffered any loss of appetite. These facts, observed by the head nurse, an intelligent man who had lived a long time among the insane, were certainly opposed to the view that the action of the remedy was an indirect one.

"Those who suffered from gastric troubles undoubtedly emaciated to a greater extent and more rapidly, but others who were free from these disorders also lost flesh. I was impressed by these facts when I wrote my two papers, recently published, on the sedative action of duboisine, administered in continuous and interrupted doses to the insane (*Archives de Neurologie et France Médicale*, 1893). Since that time my more recent researches on the hypnotic properties of this substance have furnished me with fresh arguments in favor of its indirect action upon nutrition through the medium of gastric disorders. This is confirmed by the fact mentioned above, that injections administered in the evening, at seven o'clock, neither interfered with digestion nor with the nutritive functions.

"Of the thirty-one cases to which duboisine was administered in this manner, eight (twenty-six per cent.) increased in weight and eighteen (fifty-eight per cent.) neither gained nor lost,—that is to say, in eighty-four per cent. nutrition did not suffer. This result is, besides, confirmed by the fact that the five patients who lost weight were precisely those who suffered from gastric disorders. Two of them suffered from vomiting, and two others who did not vomit lost appetite to a considerable extent and partook of very little food. The fifth, an epileptic, suffering from insomnia, requested that the remedy be discontinued on account of loss of appetite.

"For these various reasons I am inclined to the opinion that duboisine exerts its injurious action upon nutrition through the gastric disorders which it excites.

"The drug is undoubtedly a wonderful sedative; but if it disordered nutrition in a direct manner we would be obliged to abandon it, at least in the treatment of insanity, in which the first indication is to fortify the nutrition. If, on the other hand, it exerted an injurious effect on nutrition through its interference with digestion, there would remain a hope of finding a method of administering it without this result.

"With this object in view, we have undertaken a new system of researches, which consists in administering the drug at seven o'clock in the evening and at noon. Whatever may be its result, it is certain that duboisine exerts directly or indirectly a decidedly unfavorable effect upon nutrition, and the knowledge of this fact is important to the appreciation of the indications and contraindications of the drug. The above-mentioned physiological effects of duboisine do not occur with equal frequency,

while some of them, such as sedation, reduced arterial tension, sluggish pupil, elevation of temperature, somnolence, dryness of skin and mucous membranes, are almost constant; the others differ widely in each individual; in fact, there are few remedies whose action seems to depend so largely upon individual idiosyncrasy. Even in the same subject the physiological action of the drug differs from day to day without any apparent reason. The elevation of temperature, which was constant, was generally slight, never exceeding seven-tenths of a degree above the normal point; the increase in the number of respirations was in many cases only two or three above normal. On the other hand, certain decided alterations of function were quite rare, such as flushing of the face, vertigo, and thirst. The different effects of the remedy seemed to depend somewhat upon the mental state of the patient; the hysterical patients seemed to be most susceptible to the drug; the maniacal cases were the least affected by it. Between these two groups come the paralytic and the epileptic, the latter perhaps being more susceptible to it than the former.

"We have already mentioned that the different results varied according to the mode of administering the remedy. We have seen that the digestive disorders seem to depend upon the time of its administration. I will add that hypodermic injection is superior to its administration by the mouth, both as regards the rapidity of its action and its efficacy. It is also better to give the drug interruptedly than continuously, in order to avoid a tolerance of it; and, finally, it is better to give it in fractional doses than in a single dose.

"The time at which the various physiological effects of the drug manifest themselves, their duration, and their persistence have offered some diversities worthy of mention; the modification of the dynamometric force, of sensation, of the reflexes, and of the temperature have been early and persistent; they appeared immediately after its administration, reappeared at each successive dose, and continued for three or four hours. The effect upon the secretions, though more tardy in appearance, was of longer duration. On the day after the drug was taken the patients complained of dryness of the throat. In certain cases vertigo and hallucinations of the sight were of regular recurrence, causing them to refuse to submit to the medication. Happily, these cases were exceptional. The sedative effect of the drug is at the same time the most persistent and the one of which the patient first acquires a toler-

ance. Sometimes it has lasted during the entire period of its administration, while again the tolerance of it has become so great as to resist the largest doses. Of twenty-two cases in which the calmative effects were at first decided, a tolerance was acquired in eight (thirty-seven per cent.). In two of these this took place in four days, in three in six days, and in one not until after the lapse of twelve days. In such cases the sedative action of the drug may be restored by ceasing its continuous administration and lengthening the interval between the doses. Its hypnotic action has been much more prompt and less liable to be weakened by tolerance. The most tardy effect of the drug and at the same time the most tenacious is its action upon the stomach, manifesting itself first by anorexia, later by vomiting and loss of flesh, phenomena upon which we have already laid sufficient stress."

#### TREATMENT OF THE TOXÆMIA OF PREGNANCY.

In the February number of the *American Journal of the Medical Sciences*, E. P. DAVIS, of Philadelphia, contributes a valuable paper on this topic.

The treatment of the toxæmia of pregnancy must be instituted with reference to promoting the action of five excretory organs,—namely, the kidney, liver, intestine, skin, and lungs. The usual precaution of limiting the patient's diet largely to milk is, of course, indicated; but when nutrition suffers from the monotony and distastefulness of milk, there should be no hesitation in giving a more liberal diet to preserve the patient's strength. Fish and oysters, the white meat of fowls, fruits in abundance, and the more digestible sorts of bread, fresh and nutritious, form a usually acceptable diet. Pure water must be taken, but not in excess, as it is possible to seriously embarrass the kidneys by a sudden increase in the amount of fluid taken. Tea had better be omitted, while the diuretic effect of coffee is sometimes of value.

The literature of the subject affords abundant evidence that the liver has an important part in the production of this condition. However theory may dictate regarding treatment, the writer has no doubt of the practical advantages following the occasional use of calomel and soda to promote the action of the liver and kidneys as well. This should be followed by a purgative producing free and liquid stools. Salts of potassium should be avoided,

because of the irritant properties possessed by potassium when introduced into the fluids of the body. Colocynth is a convenient and efficient drug for this purpose. The bath and pack are the only efficient remedies which experience suggests in promoting the excretory action of the skin. Where the hot bath is depressing, the warm bath, accompanied by the ingestion of a small quantity of hot water, is of decided value. This may well be taken just before retiring, thus avoiding the danger of exposure to cold following the bath. Light woollen should be worn next the skin in summer or winter. In addition to the bath, in severe cases the pack in sheets wrung out of hot water, or the hot-air bath, is of the utmost value. Further, where a condition of moderate toxæmia exists, or continues a long time, yielding to treatment with difficulty, great benefit will be found from gentle massage; this should include the limbs and back, avoiding the abdomen. It may well be given at night, followed by the bath, and often secures for the patient a refreshing sleep.

The importance of fresh air in abundance for these cases is sometimes overlooked; in summer, conditions for obtaining good air are very commonly present, but in winter it is necessary to attend to this point.

Especial attention is called to the diagnosis of toxæmia from the general condition of the patient's nervous system. A careful and experienced observer can detect a very different condition in the toxæmic patient from the simple nervousness and apprehension of the pregnant woman; the condition is that of intoxication, varying in degree. Thus, we recall the case of a woman admitted to a hospital, and soon after taken with severe eclampsia. After a dangerous illness of several days she recovered, having been utterly oblivious of her coming to the hospital and of her illness until she was virtually convalescent. She had been as completely intoxicated as if drugged with alcohol or opium. An interesting manifestation of this condition is afforded by the peculiar mania often seen in eclamptic cases; thus, in one case referred to in this paper, for several days before her death her delirium was a very pitiable form of mania.

The clinical picture afforded by the toxæmic condition must impress itself upon the careful observer as one of an intoxication showing itself by a disordered nervous system. We regard as cardinal symptoms of this condition the nervous phenomena already described and diminished excretion. Upon these a diagnosis is to be made and the treatment of the case

conducted. As regards the cardinal principles of treatment, we are opposed to the use of sedatives and narcotics; the patient's need is for elimination, and that must be secured as promptly as possible. The sedative effect of eliminative treatment is often remarkable. Thus, in the case reported above, she asserted that the most enjoyable features (physically) of her life during the last weeks of her pregnancy were the warm bath taken at evening and the few hours of refreshing sleep which followed. She also recognized the distinct benefit obtained by free purgation.

In the face of threatened eclampsia, our duty lies in prompt emptying of the uterus. Here an anæsthetic is often requisite at the time of labor, and the writer's preference is for chloroform. The danger of delay in emptying the uterus is too familiar to require mention, and when the patient's symptoms are not relieved by thorough elimination from the intestines, skin, kidneys, liver, and lungs, the time for delay is certainly past, and we shall not be faithful to our duty if we allow a patient to go further in this dangerous condition. The recent literature of eclampsia contains striking evidence of the value of terminating the pregnancy by dilating the uterus and removing the foetus. If this be done under anæsthesia and with antiseptic precautions, the results are sufficiently good to command a careful attention for this method of treatment. It is a mistake to employ drugs which tend to depress the patient and favor the occurrence of œdema; such is pilocarpine. When stimulation is needed, benefit follows from alcohol, digitalis, and in cases of eclampsia, when labor has terminated and exhaustion is threatened, in the hypodermic use of strychnine.

#### OXYGEN IN THERAPEUTICS.

J. N. PITT writes on this subject in the *Medical Press and Circular*. He sums up his article with the following conclusions:

1. The inhalation of oxygen is of marvellous value in some cases of severe pneumonia, especially when there is much lividity and cardiac failure and at the crisis.

It fails in other cases, and the writer is inclined to suggest that where the condition is one mainly of cardiac failure and collapse, more benefit is obtained than in cases where the serious condition is especially due to a wide-spread œdema or bronchitis; but on this difference between the two classes of cases he would be glad to learn the experience of others.

Some cases of severe bronchitis and asthma have, however, been benefited by oxygen. In one case of acute upon chronic bronchitis in an elderly lady, he saw some, though not very marked, relief of the dyspnoea.

2. In cases of empyema, pneumothorax, and pleuritic effusion great relief can be afforded to the dyspnoea and cardiac failure until operative measures are undertaken.

3. Cases of feeble patients with phthisis may be relieved, but more often there is no marked change.

4. Cases of weakly convalescents and feeble cardiac cases will often derive great benefit, and inhalations may be given periodically for weeks; but oxygen will not restore to health; it must simply be used as an adjuvant.

5. Cases of chlorosis, pernicious anæmia, and leucocythæmia receive great temporary benefit, but the oxygen must be supplemented by other drugs.

6. Conditions of asphyxia and lividity from respiratory engorgement due to cerebral failure and also coma from various causes may be relieved.

7. Its value in uræmia, though insisted upon by French writers, is still problematical.

8. It may also be of value in diminishing the risks of anæsthesia.

#### BACTERIAL TOXINES AND ANTITOXINES.

A few years ago BRIEGER (*Münchener Medizinische Wochenschrift*, 1893, Nos. 24 and 25) and his followers assumed that the bacterial poisons are ptomaines or poisonous bases. It has been seen, however, that though these bodies are of some importance, the specific action of pathogenic bacteria does not depend on them. A few years later Brieger, Fränkel, Hankin, and Martin proved the existence of toxalbumins in artificial cultures of pathogenic bacteria, and it has since been shown that these bodies are the specific bacterial poisons. It may be mentioned here that Roux and Yersin were the first to show that the specific diphtheritic lesions may be produced by sterile bacterial solutions. The bacterial toxins have been described as toxopeptones and toxalbumoses, but whether this is true is still a matter of doubt, and as it is possible that the toxins are thrown down with pre-existing albumoses or peptones, it is better to adhere to the name toxalbumins. Now, Brieger, Fränkel, and others assumed that these toxalbumins are formed from the albuminous substances of the body by means of bacterial fermentation. Buchner, however, considers them to be direct products of the bacterial

cells, and proved this for tetanus by growing the bacillus on a solution of asparagin. Filtered asparagin cultures produced the typical tetanic lesion in animals. The toxalbumin could not have been formed by a splitting up of the asparagin, but must have been derived directly from the bacterial plasma. We cannot as yet separate these toxalbumins in a pure state, since alcohol, ether, etc., will also precipitate other albuminous bodies. We find, however, that they react like the enzymes and so-called alexines or protective proteids. In a moist condition, a temperature of 55° to 70° C., as a rule, destroyed them, while in a dry state they resist much higher temperatures, and substances which limit the action of water will increase the resistance of these bodies (neutral salts, especially the sulphates of alkaline bases). Their physiological action in most cases is slow. Thus, the toxine of tetanus produces the typical symptoms in from eight hours to two or three days.

Now, what do we know of the antitoxines? 1. Their action varies with the quantity administered. 2. It has been assumed by Behring and others that the antitoxines and the toxins neutralize each other, forming a new atoxic compound or substance. This is not true, because if we administer to a mouse a mixture of toxine and antitoxine, in such proportion that they exactly "neutralize" each other, the animal does not succumb, but at the same time a certain amount of immunity is established. The antitoxine is, therefore, stored up in the organism after the toxine has been rendered harmless. It has been assumed that the toxine has been destroyed by the antitoxine, but that the latter remains behind in an active condition. But if this were so, then one and the same quantity of antitoxine should be able out of the body, in time, to destroy a further quantity of toxine than it has already destroyed. Experiment shows that this is not so. If we make an exact mixture of toxine and antitoxine, such that when injected into mice it will not produce death, but is just neutral for mice, and then inject it into guinea-pigs (which are more susceptible towards tetanus than mice), we shall find it still poisonous for the same weight of guinea-pig; hence the toxine and antitoxine do not react directly on each other either *in vitro* or *in corpore*. The antitoxine acts by immunization, and has no actual curative action, and since guinea-pigs are more sensitive, they require a larger dose of antitoxine than mice. Buchner concludes by saying that the antitoxines are probably bacterial products. This, like all Buchner's work, is

extremely suggestive, and opens up fresh questions in regard to the true appreciation of the serum or antitoxic treatment.—*Medical Chronicle*, vol. xix., No. 1.

#### THE EARLY TREATMENT OF CARCINOMA UTERI.

KELLY contributes a valuable summary of this subject to the *New York Medical Journal*.

The large number of cancer cases constantly applying to Kelly for relief have induced him for the past three years to adopt certain stringent rules with regard to his own patients, which he has taught for the same period in his lectures at the Johns Hopkins Hospital.

The end in view is twofold. First, by treating cervixes liable to become cancerous, and thus prevent the formation of this neoplasm; and, secondly, to detect cancer of the cervix at a sufficiently early date to successfully eradicate the disease.

1. It is the duty of the obstetrician to see each patient at his office from two to three months after her confinement, and there to examine and make a careful record of the condition of the pelvic structures, stating accurately what lesions have been produced by the confinement.

2. Cervical lacerations should be carefully described, noting the position and depth of the tear and the appearance of the lips. Lacerations require no treatment when the lips are thin, uninfiltated, and lie together. Thick, infiltated, and everted lips associated with cervical catarrh call for depletory treatment, followed by repair of the laceration.

3. Every woman who has passed thirty-five years of age and has borne a child should have this examination made without delay by a competent physician, and if the cervical lips do not appear perfectly sound she should be kept under observation and examined at intervals of from six to eight months.

4. Every woman over thirty-five, with a cervical tear, should be examined at least once a year for ten years, or longer, if the appearance of the lacerated area is not perfectly healthy.

5. These rules apply with special force to patients whose family history shows a marked inclination to cancerous diseases.

If these rules are conscientiously observed there is not a shadow of doubt but that thousands of lives would be saved yearly in this country alone by timely interference with a disease so markedly local and accessible in its origin.

The author states that he feels that while we

are searching for a cure for cancer, the line of progress in the immediate future for the gynecologist is clearly in the direction of prophylaxis and anticipation, either preventing or discovering the malady in its earliest stages.

#### THE TREATMENT OF ITCHING.

In a valuable paper upon this important clinical question, BRONSON, of New York, contributes his views to the *Medical Record*. In the class of remedies to allay local irritations he includes all such remedies as directly tend to prevent itching. These will include, first of all, such as directly tend to prevent scratching. To admonish the patient to refrain from this is usually of little avail. Restraint may be possible during waking hours, but at night, when the trouble is always at its worst, and especially during the state of somnolence midway between sleeping and waking, no will-power can prevent it. It can only be avoided by first mitigating the *besoin* through the aid of antipruritics. It is of some advantage, however, for the patient to know that relief may often be obtained through other tactile diversions than those which are effected by the sharp finger-nails, as, for example, simply by firm pressure of the part, or by stroking the itching surface with the finger-pulps, or with a soft cloth or brush (especially if first lubricated with vaseline), using some pressure, but without rapid motion. Irritating contacts of all sorts should be most scrupulously avoided. Attention should be given to the under-clothing. Woollen clothing is almost never tolerated. The clothing next the skin should be of the softest material,—cotton, linen, or possibly silk. Of further importance is the avoidance of immoderate temperatures, whether of heat or cold, and especially of sudden changes, which are peculiarly apt to excite itching. The temperature of the surface should be kept as equable as possible.

The local excitants may not only be extracutaneous, but also intracutaneous. Often they are incidental to the trophic changes of one of the so-called pruriginous diseases, in which case the treatment of the pruritus is included in that of the disease of which the itching is a symptom. When they arise from toxic materials conveyed to the skin by the blood, we endeavor to eliminate these materials by depurative remedies, more especially diaphoretics and diuretics, while disturbances of the nerve-terminals that are directly transmitted from the interior are best relieved by means of the substitutive irritants.

These measures failing or proving insufficient to secure the desired rest, it becomes necessary, in pursuance of this object, to have recourse to certain sedatives. Some of these, that are used internally, are designed more particularly to neutralize the hyperæsthesia; others, including both internal and external remedies, serve rather to directly annul the pruritic excitement.

*Sedatives.*—Used internally these are apt to be disappointing. The degree of general sedation that is required to affect the nerves of the skin in so intense a disturbance as pruritus often is, affords a sufficient reason why this method of treatment is usually objectionable. Further than this, the depressing and atonic after-effect on the nervous system tends to exaggerate the general hyperæsthesia, which is already essentially an atonic condition, and thereby increase the tendency to itching. Especially objectionable on this score are most of the narcotic sedatives. The bromides, on the other hand, are often indispensable, and may be required in liberal doses. It is important to avoid the enervating effects of loss of sleep, and for this purpose sulphonal or some other hypnotic is occasionally needed. In connection with this class two internal remedies, which have been especially recommended by Bulkley, are here worthy of mention. They are cannabis indica and gelsemium. The former is known to be a cutaneous anæsthetic as well as analgesic, and by virtue of the former quality should be useful in pruritus. Whether its usefulness in this disease is chiefly owing to this or to another quality, which will be referred to later in connection with the sensory stimulants of the next following class, is uncertain. Gelsemium has proved of benefit in some cases (more especially, according to the writer's experience, in protracted cases of urticaria), but the doses required are so large as to forbid their long continuance. It will be referred to again under motor depressants. Finally, the antipyretics phenacetin and antipyrin have some effect upon pruritus, though less than upon the sensation of pain.

The local sedatives used in this disease are generally far more satisfactory in their effects than the remedies just considered, especially where the disease is limited in extent. They are for the most part agents that tend to retard vital action. The fact that many of them are antiseptics probably implies something more than mere accidental coincidence. Under both aspects their effect is to depress, if not impair, vitality; incidentally, they are nerve-depressants. Acting upon the superficial

nerve-endings, they tend to retard the so-called "nerve vibrations" or molecular movements. How they exert this action through the intact epidermis is somewhat difficult to understand, but of the effect produced there can be no question. Typical among the remedies of this class is the group which includes carbolic acid, salicylic acid, salol, and thymol, all antiseptics, and all having undoubted virtues as antipruritics.

Carbolic acid, the most important member of this group, is perhaps, all considered, the most reliable and most generally useful antipruritic which we possess. It was well named by Unna "the opium of the skin." In pure solutions, or in combination with other remedies, and even when comparatively weak, its quieting effect on pruritus rarely fails. The two- to five-per-cent. solutions which are most commonly employed, though often of benefit, do not, however, bring out the full antipruritic effect of which this drug is capable. Watery solutions require to be used of less strength than those in oils or fats. They are more apt than the latter to be corrosive, and also, being more quickly absorbed, are more liable to be followed by general toxic effects. For these reasons carbolic acid is preferably employed in oils or ointments, for, though the absorption is slow, the effect passes off less quickly, and the stronger solutions are comparatively safe. With proper precautions as to its use as an oily solution of from twelve and a half to twenty-five per cent., it may be used with perfect impunity, provided the area to which it is applied is of moderate extent.

The following "antipruritic oil" has been largely employed by Bronson for years, both in the local and in the so-called universal forms of the disease, with no more untoward results than now and then a trifling dermatitis, when through oversight the patient has been allowed to make the applications too frequently, or has continued them too long. The formula is,—

R Acid. carbolic., ʒi to ʒii;  
Liq. potass., ʒi;  
Ol. lini., ʒi. M.  
Sig.—Shake before using.

An alkali and an effective keratoplastic agent (linseed oil) serve both as adjuvant and corrigent to the action of the carbolic acid. To correct the disagreeable odor of the linseed oil, a drop or two of the oil of bergamot may be added.

Salicylic acid and salol, though less energetic in their effects, act similarly to the carbolic acid. They may be used in combination

with other drugs, or by themselves in oil or ointments, or sometimes alcohol, and also in superfatted soaps.

Thymol, which is a cutaneous anæsthetic as well as antiseptic, is also in certain cases of universal pruritus an admirable antipruritic, but, on account of its irritating effect, cannot be used where the skin is very sensitive. It is well combined with menthol in a three-per-cent. (of each) alcoholic solution. Doubtless other remedies of like character might with advantage be added to this group.

The corrosive chloride of mercury is another well-known antiseptic which has also a reputation as an antipruritic. It is difficult to explain the latter action, except by regarding this agent as a local sedative by virtue of its hostility to all forms of life and its ability to retard excessive vital action. The marked anæsthesia of the skin that is produced by concentrated solutions is doubtless due to this property.

Certain other local sedatives of the skin, though not in the antiseptic group, yet apparently owe their effect to a similar retardation or arrest of molecular movement in the affected sensory nerves. Such is cocaine. The decided anæsthetic action of this drug upon mucous membranes, upon abraded cutaneous surfaces, or when used subcutaneously, would seem to indicate it as a specific in pruritus. For two reasons it has proved disappointing. First, because of the difficulty of making its action felt through the intact epidermis; and, second, for the reason that any tissue, when long or frequently subjected to its action, suffers a certain atony and enervation that seem to render it more predisposed than before to the irritation or irritability the drug was intended to alleviate. This latter is a common effect of prolonged use in the eye or nose and after prolonged use in pruritus progenitalis. These objections by no means preclude its use entirely. It is often resorted to with most satisfactory results in localized forms about the mucous orifices, upon raw or abraded surfaces, and sometimes with appreciable effect even where the epidermis is apparently intact.

Other sedatives of this class are cyanide of potassium (1 drachm; water, 1 pint), chloroform (1 drachm; glycerin, ½ ounce; water, 8 ounces), and camphor in combination either with an inert powder or with chloral, the mixture being properly diluted. It is probable, however, that the last-named remedies act not only, often not chiefly, as sedatives, but partly as substitutive irritants. Of a somewhat similarly complex nature is the antipruritic effect of hot

water, which calms the nervous excitement, apparently not only by direct sedation of the sensory nerves, but also by its general relaxing effect, removing pressure or constriction of the nerves; and, furthermore, at the beginning, at least, it is a powerful substitutive irritant. To be effective, the temperature should be over 100° F., or as hot as can be tolerated, and the applications should be prolonged for several minutes.

It is evident that the impaired conductivity of the sensory nerves with hypopselaphesia, which, as shown, is in greater or less degree an essential condition of the pruritic sensation, though it is not necessarily antipathic to the hyperæsthesia, nevertheless affords special and independent indications for treatment. While the condition of hyperæsthesia calls for depression, or at least repression, that of hypopselaphesia demands a certain kind of stimulation; hence we distinguish in the therapeutics of pruritus a third class of remedies.

---

#### THE TREATMENT OF FIBRINOUS PNEUMONIA BY LARGE DOSES OF DIGITALIS.

BELLOTTI (*Raccoltore Medico; Rev. Internationale de Bibliographie Médicale*) confirms his previous experience, and that of Filk, Petrescu, and other observers, regarding the good results obtained in the treatment of fibrinous pneumonia (diplococcus of Fraenkel). The author advises the simultaneous use of a milk diet and, in certain cases, general bloodletting. Large doses of digitalis are necessary in pneumonic patients in proportion to the gastric catarrh present and the diminution of hydrochloric acid, both of which phenomena tend to lessen the absorption of material by the portal circulation. On the other hand, certain active principles of digitalis exercise on the liver a special function, and a decided one on the pneumotoxines elaborated by the diplococcus. The medium dose employed by the author was 4 grammes of digitalis, in the form of infusion, administered in separate doses. He advises, again, the addition to the infusion of a little mucilage of gum arabic and laudanum, in order to avoid the untoward effects that may arise.

---

#### GUAIACOL PAINTINGS AND THEIR ANTI-PYRETIC ACTION.

Guaiacol paintings have been employed in twelve febrile cases by MONTAGNON (*Loire Médicale*, No. 8, 1893; *Rev. Intern. de Bib-*

*liog. Médicale*). The method caused a lowering of the bodily temperature, but the effect was not constant and seemed to depend upon individual susceptibilities, and the part of the body used for the application of the medicament. The groin appeared to be the most favorable region for the guaiacol paintings. Generally, the reduction of the temperature occurred in one hour after the application of the remedy, and lasted from two to three hours; after this the temperature began to ascend again. The most effective doses were 2 grammes, sometimes 3 grammes, never going beyond this limit. The local use of the drug, according to the author, is badly borne by advanced phthisical patients, but better tolerated in the earlier stages of the disease. The action of guaiacol seems to be a general one and independent of the true cause of the fever; the effects are not due to the absorption of the medicament by the lungs. The paintings were frequently accompanied with sweating, chills, and tremors, especially in advanced cases of phthisis laboring under adynamic conditions. In these cases the reduction of the temperature was followed by phenomena of collapse. After the employment of the drug, the patients complained of general malaise, and never felt relieved. The author further affirms that untoward effects upon the skin, under the influence of guaiacol, are rare, provided the remedy is pure and in applying it not much friction is practised. Children are more susceptible to guaiacol than adults. The drug acts in a similar manner—that is, as an antipyretic—when administered by rectal injections.

#### THE VALUE OF VARIOUS DIETS IN CHRONIC BRIGHT'S DISEASE.

In the *Medico-Chirurgical Transactions*, of London, DR. W. HALE WHITE contributes a valuable paper upon this subject. After giving the opinion of a large number of well-known authorities upon the value of diet in chronic Bright's disease, he says that he might quote many other authors, but thinks that he has referred to sufficient to show that they are by no means unanimous as to the best diet to give patients suffering from chronic Bright's disease. For this reason, and also because many have used too few cases for the results to be conclusive, and others have relied largely on *a priori* considerations, it seemed to him worth while to carefully analyze the urine and note the symptoms in a series of cases. We know so little that is certain about the cause of the

serious symptoms of Bright's disease that it is only by actual trial that we can find out whether any particular diet is valuable.

Milk is very frequently recommended, and it has been claimed that it will do good, for the following reasons:

1. It is said to diminish the amount of albumin. In the first place, the figures the writer gives later on show that this is very far from being always true, at any rate in chronic interstitial nephritis; and some of Grainger Stewart's cases point in the same direction, for on ordinary, large, milk, or low diet the albuminuria remained unchanged, and even partaking abundantly of eggs did not increase it. Such experiences as these mean either that the reported cases in which it is said that the albuminuria was diminished by a milk diet belong to a different category, or else that they were improving in this respect at the time that the milk diet was started.

Then, secondly, even if milk did decrease the albuminuria, we have in many cases no proof that this is of any benefit. Patients who are very ill may lose only one or two grammes of albumin a day in the urine. This cannot of itself be of much importance; the absorption from the intestine of a very little more albuminous material would, if not lost in some excretion, quickly make up the deficiency. Then, again, people who suffer from cyclic albuminuria are often none the worse for it, nor does the loss of albumin in other ways, as by epistaxis, or by means of a discharge of pus, produce any symptoms comparable to those of Bright's disease. Indeed, the majority of persons who pass albumin in their urine have not got Bright's disease at all, but are suffering from heart-disease, pyuria, specific fevers, etc. Lastly, albuminuria is probably to a large extent only a local sign indicating disease of the secreting renal epithelium, and not a general blood condition. All these considerations indicate that, even in cases of Bright's disease in which the loss of albumin is considerable, this of itself is not really quite so important as is usually thought. Surely, if it were, restricting the diet to food containing less albumin than ordinary diet ought to be harmful to the patient, for not only would he be losing more albumin than in health, but he would be taking in less, and the author later on shows that, if we may assume that when more proteid is taken by persons suffering from increased albuminuria, the increased amount of proteid taken very much more than compensates for the increased albumin passed in the urine, and in some cases of Bright's disease the albuminuria is even less

on full than on milk or farinaceous diets. No doubt the restriction of the saccharine food in diabetes would by analogy lead us to restrict the albuminous food in albuminuria, but analogical reasoning of this sort is most fallacious. It is quite sure that the significance of albuminuria in Bright's disease is overestimated, and treatment directed immediately to it is unsound, especially when, as in the case of milk diet, although it frequently fails to diminish the amount of albumin passed, it often sets up loathing and disgust.

2. Some authors urge that milk is easily digested and absorbed. Often this is directly contrary to fact. Many writers have noticed, the author among the number, that patients who have chronic Bright's disease and are fed solely upon milk often suffer from indigestion; and, as just mentioned, they get to positively loathe the milk, which also has the additional disadvantage that it leads to constipation.

3. It is stated that milk does not irritate the kidneys; but before this statement can have any value it must be shown that ordinary food does irritate them, and this has not yet been done. It is curious that if milk is such a particularly bland and unirritating substance to the kidneys, these organs should, in young children, be so frequently streaked with urates.

4. Milk is often said to be diuretic. For instance, the patient whose case is related by Drs. Sparks and Mitchell Bruce passed more urine on a milk diet than on ordinary diet together with a large amount of water; but as he passed more urine in this combination than on ordinary diet alone, it is highly probable that the diuretic effect of the milk was in part due to the quantity of water in it. Some of the cases related by White show that milk is usually, but not invariably, diuretic. Of Granger Stewart's cases, milk did not act as a diuretic in those with parenchymatous nephritis, nor did it in the chronic cases. Thus we see that milk is neither a powerful nor a certain diuretic, and we must remember that, even if it were, it is doubtful whether it would be a good thing to give diuretics in Bright's disease.

5. Lépine has urged that milk is beneficial for Bright's disease because it contains no toxic substances. But, for all we know, it may contain poisonous substances which, although excreted in health, are retained in the blood in Bright's disease. His supposition that it aids the elimination of toxic substances in Bright's disease is without a shadow of proof. It seems futile to argue in this way about the toxine of Bright's disease when we do not know what it is.

The view that a diet containing very little proteid is beneficial for Bright's disease is probably due to a lingering survival of the false belief that the urea which is not excreted in Bright's disease is the cause of the symptoms of uræmia.

We thus see that all the *a priori* considerations which have been put forward for giving milk in chronic Bright's disease have in themselves no value, and similar objections could be urged against the reasons which have led to the belief that other particular diets would be beneficial. Therefore all that is left to us is to examine cases.

Holding such views, therefore, he proceeded to analyze ten cases which were under his care, giving them three forms of diet,—a milk diet, consisting of three pints a day; a farinaceous diet, consisting of twelve ounces of bread, one ounce of butter, two pints of milk, and one pint of beef-tea; and a full diet, consisting of twelve ounces of bread, one ounce of butter, half a pint of milk, half a pound of potatoes, and six ounces of meat. Sometimes rice-pudding was made with a half-pint of milk, or the patient was given half a pint of mutton-broth. Tea and sugar were allowed in both the farinaceous and full diets. The points which he examined into were the quantity of urine passed, its specific gravity, the amount of albumin, the amount of urea, and the general condition of the patient. He reaches the following conclusions:

We see that, on the whole, an ordinary full diet is the best for this malady, for,—

1. It does not increase the liability to uræmia.

2. The general condition of the patients improves upon it, and they feel stronger and their circulation is better when they are taking it than when they are on milk or farinaceous diet.

3. A saving of albumin to the body is effected by it, for, even if the output of albumin is increased, which it very often is not, more than sufficient extra proteid is taken on the full diet to compensate for any extra loss in the urine, assuming, and there is no evidence to the contrary, that more proteid is absorbed upon full diet than upon milk.

4. The effect of diet on the excretion of urea is too uncertain to be any guide to us, but there is no evidence that in this respect full diet is harmful.

5. There is no evidence that full diet contains, or specially leads to, the formation of any toxic principles which are harmful in chronic Bright's disease.

6. This diet prevents the repugnance felt by

these patients to farinaceous diet and their loathing of milk.

The only thing against it is that rather less urine is passed upon full diet than upon milk or farinaceous diet. But this difficulty can be overcome by drinking an extra quantity of water daily, and it must be remembered that in many cases of chronic Bright's disease diuresis is already profuse. It may be well to point out that as the ten cases which form the basis of this paper were all patients who were sufficiently ill to require admission to the hospital, it is quite possible that some of the conclusions might not apply to patients who had Bright's disease in a mild form or to those accustomed to overeating.

#### EXCLUSION OF DAYLIGHT IN THE TREATMENT OF SMALL-POX.

FINSEN (*Hosp. Tid.*, No. 27, 1893) has made some observations on the effect of light on the skin. He referred to the good results obtained by Black and others by the exclusion of daylight in the treatment of small-pox, but argued that, as Widmark has shown that it is the ultra-violet rays which have the strong chemical action, it is not necessary to exclude the daylight, but by using red curtains tightly drawn, or red window-panes, the injurious effects of the light can be prevented. The correctness of this hypothesis was proved by Svendsen, of Bergen, who last summer treated four cases of small-pox in unvaccinated patients by covering the windows with thick red woollen curtains. The patients escaped the suppurative stage; there was no rise of temperature, no oedema. The patients passed from the vesicular stage, which was slightly prolonged, into convalescence, and escaped scarring.—*British Medical Journal*, February 17, 1894.

#### PENTAL.

PHILLIP (*Zeitschrift f. Kinderheilk.*, Bd. iii., 4, 1893) states that during the preceding twelve months chloroform and pental were the only anæsthetics used in the Kaiser Friedrich Children's Hospital, Berlin, local anodynes having been found impracticable in the case of children. The following were found to be the principal advantages of pental: Extraordinarily rapid narcosis; rarity of a period of excitement, which, if present, ceased with absolute narcosis; immediate recovery of consciousness after removal of the mass; and absence of any

unpleasant after-effects, such as are caused by chloroform. No action on the heart was ever observed, but in some patients arrest of respiration and cyanosis occasionally appeared, when removal of the mask sufficed to restore the natural color. The author attributes the cyanosis, not to any toxic action on the respiratory centre, but to tonic contractions of the diaphragm and glottis. In twenty-one cases the urine was subsequently examined for albumin, but only once was a trace found, which disappeared on the third day; this occurred in a tuberculous child after a prolonged operation. The majority of the operations lasted from ten to thirty minutes, from thirty to sixty cubic centimetres of pental being required. In conclusion, judging by one thousand narcoses, pental is, with certain exceptions, always able to replace chloroform, being, moreover, less dangerous and without after-effects. In the above-named hospital pental is now looked upon as an indispensable drug, but during its use all precautions should be taken as when administering chloroform.—*British Medical Journal*, February 17, 1894.

#### THE TREATMENT OF SCLERODERMA.

According to the Berlin correspondent of the *Medical Press and Circular* for February 14, 1894, at the last meeting of the Dermatological Society, SCHUTTE showed a man whose illness began with pain in the knees and elbows, and with the formation of red, painful rhagades. The disease progressed slowly over the lower extremities and the right arm, and diminished greatly the usefulness of the limbs. Several methods of treatment had only a passing effect. On admission, the skin over the lower extremities and the buttocks was smooth, shining, hard, and firm; bright and dark pigmented spots were irregularly scattered about. The patient could scarcely move the limbs; he mounted the steps as if the knees were ankylosed. The temperature of the skin was lowered. The treatment consisted of lengthened sitz baths, with succeeding massage with five-to ten-per-cent. salicylic vaseline. The salicylin was increased as improvement progressed. The patient gradually regained power of movement of the extremities. A small quantity of salicylic acid could be determined in the urine, so that some must have been absorbed through the skin. The favorable influence of such treatment has been previously demonstrated in the case of a female shown to the Society. In that case the improvement had been maintained.

The speaker also showed a little girl, aged ten, in whom the method of treatment described had had good results. The case was, however, less convincing, as the child had been treated as an out-patient and electricity had been employed on account of facial hemiatrophy.

LEWIN thought, as regarded the result of treatment of scleroderma, that the spontaneous variations in the complaint should be taken into account.

LASSAR replied that the case showed the slowly progressing improvement was opposed to one independent of treatment.

### PRESCRIPTIONS.

For impetigo :

℞ Adipis,  
Vaseline, of each, ℥iii;  
Acidi salicylatis, gr. vii;  
Zinci oxidi, ℥iss;  
Plumbi diacetatis, gr. v. M.

The following is also useful in impetigo :

℞ Vaseline, ℥iiss;  
Acidi borici, ℥ss;  
Zinci oxidi, ℥ss;  
Acidi salicylatis, gr. vii. M.

An antiseptic powder :

℞ Iodoform, ℥xxxi;  
Pulv. benzoini, ℥xxxi;  
Quinquinae, ℥xxxii;  
Magnes. carb., ℥xxxi;  
Ol. eucalypti, ℥iv.

Sulphur lotion for acne :

℞ Sulphuris sublim., ℥iss;  
Sp. camph., ℥iv;  
Aq. destill., ad ℥ii.

Lotion for acute eczema in infants :

℞ Lot. nigræ, ℥iv;  
Liq. calcis, ℥iv;  
Mucil. tragacanth, ℥i.

An application for recent ringworm :

℞ Thymol, ℥ss;  
Chloroformi, ℥ii;  
Ol. olivæ, ad ℥i. M.

To be applied night and morning.

For laryngeal phthisis and dysphagia :

℞ Cocainæ hydrochloratis, gr. x;  
Acidi borici, gr. iv;  
Glycerini, ℥xv;  
Aq. destill., ad ℥i. M.

To be applied to the throat when necessary.

A local application in diphtheria :

℞ Acidi salicylatis, 3 parts;  
Alcohol, 20 parts;  
Resorcin, 2 parts;  
Glycerini, 10 parts. M.

The affected parts to be touched twice daily with the application.

A sedative cough mixture in phthisis :

℞ Codeinæ sulph., gr. iii;  
Liq. atropiæ sulph., ℥xii;  
Liq. strychniæ, ℥i;  
Syr. tolutani, ℥iss;  
Infus. rosa acid, ad ℥vi. M.

A tablespoonful in a wineglassful of water every four or six hours.

—*Medical Press and Circular*, February 14, 1894.

### ON SOME CASES OF ACUTE INTUSSUSCEPTION IN CHILDREN.

In the *British Medical Journal* for February 17, 1894, BARKER concludes an article with the above heading with the following statements :

It is interesting to note that out of the six operated on, three at least could not possibly have been reduced by inflation or injection; for in one the intussusception was high up in the small intestine, and in the other two several inches of ileum were prolapsed through the ileo-cæcal valve. In all the seven it may be said, then, that the injection failed, and in three it must have failed. In spite of this, laparotomy saved three out of the six operated on. But when we come to examine the causes of death in the three who died after operation, it is clear that the result was due in each case to the operation not having been done soon enough. In one of them, when the abdomen was opened, the intussusciens was sloughing largely, in two places forming wide perforations. In another the gut was not actually sloughing, but was rotten from strangulation and incapable of being reduced. In the third a small slough was in process of formation at the time of operation, which gave way a day later, with fatal perforation. All these cases might have been saved by a somewhat earlier laparotomy; they could not have been saved by injection.

In addition to the cases now related in his present article, Barker has collected all those of children treated for acute intussusception in the surgical wards of University College Hospital from the year 1877 to the end of 1893. These, with seven of his own, form a list of twenty-five cases, all under thirteen years of age. Of these, thirteen recovered, twelve died. The treatment adopted in nineteen was either

manipulation (one) or injection of air or water (seven), followed in case of failure by laparotomy (eleven). In five cases laparotomy was done without any previous attempts at reduction; of these, two were of the enteric variety; four died, one recovered.

Of the nineteen cases where injection and manipulation had been tried, followed by laparotomy where necessary (eleven), seven died and twelve recovered. Of these twelve recoveries, seven followed manipulation or injection alone, five followed laparotomy where these had failed. Of the eight fatal cases, seven deaths followed laparotomy, one followed repeated injection. Taken in the gross, there were therefore seventeen laparotomies with eleven deaths, and eight injections or manipulations alone with one death.

From all this it would appear that the practice at University College Hospital for many years has been to try injection of air or water in all cases not recognized at once as desperate, and when these means have failed, to proceed to laparotomy at once. By these measures thirteen out of twenty-five cases have been saved, and probably a larger number would have recovered if the laparotomies in several cases had been done earlier.

Of course the majority of the recoveries are credited to the injection method, inasmuch as laparotomy was only resorted to when the latter had failed. In other words, abdominal section was only done in bad cases; indeed, in several cases the condition was desperate. In the face of this fact it is encouraging to note that out of seventeen cases treated by laparotomy, six recovered; although several were in a very bad condition at the time of the operation, in some the bowel being actually gangrenous. If we subtract these cases from the list, the proportion of recoveries is fairly good considering the gravity of the condition.

The conclusions, then, which seem deducible from a study of these and many other records, appear to be as follows:

1. That in all cases of intussusception in children injection of water or manipulation should be at once resorted to *if the patient is seen within a few hours of the onset of the strangulation.*

2. That if these means fail after a fair trial, not too much prolonged, laparotomy should be at once done as the safest treatment.

3. That there is a certain proportion of cases among all the varieties of intussusception which no amount of injection will relieve, or in which injection would be dangerous, and these can only be dealt with by opening the abdomen.

#### EXPERIMENTAL RESEARCHES ON ANTISEPTICS IN OCULAR OPERATIONS AND ON THE BACTERIOLOGY OF THE CONJUNCTIVAL SAC.

MARTHEN (*Deutschmann's Beitrage zur Augenheilkunde*, 1893) continues the work of Hildebrandt and Bernheim on this subject (already abstracted in previous numbers of the THERAPEUTIC GAZETTE), and concludes that the number of microbes in a normal conjunctiva is not very great, and even a slight degree of catarrhal inflammation does not greatly increase their quantity. On the other hand, an apparently normal conjunctiva may harbor numerous micro-organisms, some of them of virulent property. This is especially true of the ciliary margin. According to Marthen, it is impossible to completely sterilize the ciliary border, even for twenty-four hours, with ordinary preparations,—sublimate, 1 to 1000 or 1 to 2000; nitrate of silver, two per cent. However, a notable diminution in the virulence of the germs is obtainable, greater than that secured by mechanical means,—e.g., bathing with a physiological salt solution. If an operated eye is bandaged with non-antiseptic materials, it rather favors the development of microbes, because it prevents their natural expulsion by the movements of the lids. The tears, according to Marthen, have the property of preventing the development of certain microbes, but others are unaffected,—for example, the bacillus prodigiosus. The experiments made with the aqueous humor from animals have not yielded positive results.

#### SUBCONJUNCTIVAL INJECTIONS OF SUBLIMATE IN OPHTHALMIC PRACTICE.

PÉRINOFF (abstract *Archives d'Ophthalmologie*, December, 1893) gives the results of his experiments, embracing one hundred and forty cases of different ocular affections, such as (1) parenchymatous keratitis, hypopyon-keratitis, and simple keratitis; (2) different forms of iritis; (3) affections of the vitreous body and different forms of choroiditis, of neuro-retinitis, and of atrophy of the optic nerve. He comes to the following conclusions:

1. Injections of sublimate merit serious attention as an excellent adjuvant in treating serious lesions of the media of the eye.

2. They should be considered as the best local treatment for lesions of the inner tissues of the eye, choroid and retina.

3. In sympathetic affections these injections deserve particular attention, since their use may prevent the enucleation of the eye.

4. The good results of solutions of sublimate under these circumstances may be due to the rapid absorption of the microbicidal solution, and, on the other hand, to a counter-irritant action, which in some way accelerates the dissemination of the products in diseased tissues. The author's method of using the injections is about the same as that employed by Darier and others. Methods and formulas are given in preceding numbers of the GAZETTE.

#### INJECTIONS AFTER THE MANNER OF BROWN-SÉQUARD IN OCULAR THERAPEUTICS.

The following extract from a report on the above subject is contained in the *Recueil d'Ophthalmologie*, December, 1893:

Darier, like De Wecker, has been in the habit of using injections of testicular essence for different ocular affections. He has not published his results heretofore on account of the inadequacy of the treatment. In tobacco, alcohol, and diabetic amblyopia he has never observed improvement. In tabetic atrophy of the optic nerve, Séquardian injections have sometimes produced improvement, just as this follows all other known methods of treatment,—for example, electricity, strychnine, stretching of the optic nerve, suspension, and antipyrin. All that he is willing to say is that the Séquardian injection is an excellent tonic, all the more efficacious when given to a reduced, debilitated, and neurasthenic organism, and the more confiding the patient is the more power it has. Mercurial treatment is a two-edged sword which yields, side by side with rare improvements, frequent aggravations, even in cases which are evidently syphilitic. It is, therefore, useful to have this additional remedy in the therapeutic arsenal.

De Wecker stated that the principal object of his communication was to demonstrate the inefficiency of Séquardian injections, so far as the ocular indications of ataxia are concerned. None the less, he recommends these injections because thereby the strength of the patient is increased, he is toned up, as it were, and there is an evident mental impression. He believes that it is easier to joke about them than it is to refute the indisputable effect of these injections under certain circumstances, especially in neurasthenic individuals, and details one case of marked retinal asthenopia in a patient of thirty-seven years of age, which was not amenable to ordinary treatment and yet was promptly relieved under the influence of these injections. Therefore, although he does not believe that

they have the slightest influence in relieving organic conditions like ataxia, he adds them to other treatment because of their undeniable tonic properties.

#### CONCERNING CATARACT EXTRACTIONS AND SUBSEQUENT DRESSING.

DR. JULIAN J. CHISOLM (*Annals of Ophthalmology and Otology*, January, 1894) sterilizes his instruments with boiling water, and, although he irrigates the conjunctival cul-de-sac with sublimated water, he doubts much whether this washing subserves any good purpose. He does simple extraction and is satisfied with it, although he has about eight per cent. of prolapse of the iris, which, however, has never caused any serious trouble if promptly dealt with. He evidently thinks, as many other surgeons do, that the operation which affords the greatest safety to the patient is a preliminary iridectomy. Operating by the simple method, he has abandoned the adhesive-strap dressing, which he formerly used, on account of the necessity of daily inspection of the operated eye, and adopts in its place a single Liebreich bandage. It is a quadrangular piece of folded muslin three inches long by two inches wide, with long tapes extending from each corner for securing it to the head. Over the closed eye is placed first a square of felted absorbent cotton, known as the cottonoid surgical dressing. This is usually wetted with a weak sublimate solution. A thin wad of cotton-wool is placed over this, and the whole secured by the single eye bandage lightly tied on the opposite temple, so as to exercise no pressure upon the eyeball. He does not consider it necessary to specially sterilize this dressing. If the wound has healed sufficiently on the third day, atropine is dropped into the eye, and on the fifth day the bandage is removed permanently. By the fourteenth day the patient can usually leave the hospital. He allows his patients considerable liberty of movement. In operating for congenital cataracts, no dressing is applied to the eye to close it up, but the patient's hands are secured lest he rub the operated eye.

#### THE TREATMENT OF INTERNAL SQUINT.

DR. HOWARD F. HANSELL (*Annals of Ophthalmology and Otology*, January, 1894) considers that the treatment of complicated internal squint includes the considerations which follow:

1. Improvement of vision.

(a) A careful and full correction of all optical defects.

(b) *Amblyopia*.—It is reported that in very early childhood amblyopia can be cured by training the amblyopic eye, by excluding the fixing eye from participation in the act of vision for days and weeks at a time by means of bandages or atropine. This method is conservative and doubtless efficacious in a few cases, and invalidates the excuse for early operation, frequently given, that the vision of the squinting eye will still further deteriorate.

(c) *The Proper Age for Operation*.—As is well known, a want of co-ordination of the eye-muscles in infants is common. A child may be several years old before it learns to bring both eyes into harness. This is a second and forcible objection to early interference. The rule usually followed is to wait until the child is old enough to wear glasses. He contends that this is too early. The patient should be sufficiently intelligent to discern double images with the tests employed and to give accurate information of their relative positions.

(d) *Hyperesophoria*.—Probably seventy-five per cent. of all cases of internal squint are complicated by an upward deviation of one cornea. It therefore is essential to successful treatment that vertical as well as horizontal equilibrium be secured. Indeed, it is not improbable that in a few cases of oblique turning of the cornea, esotropia depends upon hypertropia. This statement is corroborated, clinically, by a case reported by him in the *New York Medical Record*, August 26, 1893. Girl, aged five; hypermetropia 2.50 D., wide internal squint, fixes with R. Interni divided, under ether, August, 1891; apparent equilibrium one week later. In June, 1893, again internal squint and the same treatment. Two weeks later the squint is apparently as bad as before the first operation. He is now able to diagnose L. hypertropia three degrees; L. super-rectus divided; *the convergence becomes immediately divergence*.

He is convinced that his experience is not unique, and that convergent squint treated according to the usual and routine method is more often a failure than a success. The results amply prove that our conception of the physiology of hypermetropic squint is too limited, and that it should be extended to include the action of the elevators and depressors in conjunction with the interni.

2. *Equilibrium through Operation*.—The surgical treatment must be carried out under cocaine anæsthesia, since abolition of con-

sciousness is incompatible with scientific accuracy.

(a) Restoration of vertical equilibrium by tenotomy of the superior rectus of the upward and, if necessary, the inferior of the downward deviating eye.

(b) Restoration of horizontal equilibrium by tenotomy of both internal muscles and, if necessary, advancement of one or both externi.

---

*THE EMPLOYMENT OF AN OIL OF BINIODIDE OF MERCURY AS AN ANTI-SEPTIC IN CERTAIN AFFECTIONS OF THE EYE.*

J. BRAQUEHAVE (*Archives d'Ophthalmologie*, November, 1893) describes his experiences with an oil of the biniodide of mercury. Various maladies have been treated,—namely, squamous and ulcerated blepharitis, styes, ulcers of the cornea, and granulations. Braquehave comes to the following conclusions:

1. The treatment with the oil of biniodide of mercury—4 parts to 1000—is an excellent application for all microbic inflammations of the ciliary border, provided the area affected is first thoroughly cured.

2. This medicament may be used in ulcers of the cornea resulting from neglected traumatism, even when accompanied by hypopyon.

3. It should not be used when ulceration of the cornea is the result of an inflamed condition of the eye, as, for instance, in phlyctenular conjunctivitis.

4. It may also be tried in granular lids.

---

*A NEW METHOD OF PERFORMING JEJUNOSTOMY.*

ALBERT (*Wiener Medizinische Wochenschrift*, No. 2, 1894) reports two cases of jejunostomy performed by a method which represents a modification of that last introduced by Maydel. Maydel's operation consists in drawing out the first loop of jejunum which can be reached, cutting it across, exposing several inches of the distal end, and making a lateral implantation of the proximal end into a longitudinal slit made some distance below the seat of transverse section. The distal end is then secured in the abdominal wound; thus not only can nourishment be introduced into the jejunum, but also by means of the lateral implantation the secretions of the pancreas and liver are carried on to the ileum at the same time, and regurgitation of the bowel contents through the abdominal opening is rendered difficult. Albert's modification consists in

drawing out the first loop of the jejunum which is found, then closing by provisional suture the greater portion of the abdominal wound. The two arms of the loop thus drawn out are united at their bases by lateral anastomosis. Parallel to the first abdominal incision and one and a half inches above it an inch incision is made through the skin. From this superficial upper wound to the lower one a subcutaneous communication is established by tearing up the skin and subcutaneous fascia with the finger. Through the tunnel thus formed is drawn the convexity of the loop of jejunum, at the base of which the lateral anastomosis has been formed. The bowel is stitched in this upper skin incision, and the lower opening through which the gut passes from the abdominal cavity is closed as nearly as is possible without causing strangulation of the loop of jejunum passing through it. The skin-wound of the lower incision is entirely closed. The seat of anastomosis between the upper and lower arm of the loop lies within the peritoneal cavity, and when the apex of this loop is opened, there is provided a long sinus tightly pressed by the skin and which entirely prevents regurgitation of food. The anastomosis of course allows the normal passage of bile and pancreatic fluid.

Albert operated on two cases, one of which survived several weeks.

#### THE INCH-AND-A-HALF INCISION AND WEEK-AND-A-HALF CONFINEMENT IN APPENDICITIS.

At a meeting of the New York State Medical Society, held February 8, 1894, DR. ROBERT T. MORRIS, in a paper written under this title, stated that we had recently learned four principal things relative to appendicitis, and he was now asking the members of the profession to accept a fifth point.

1. We had learned that appendicitis was of such common occurrence that every general practitioner had many cases in his *clientèle*.

2. It was now generally known that multitudinous forms of abdominal inflammation were symptomatic of appendicitis.

3. Statistics showed that late operation did not give us much encouragement.

4. It was known that early operation or operation in the interval between attacks was attended with trifling mortality (with none at all, in his experience), but that there was danger of ventral hernia resulting from it if a long incision were made.

The fifth point was this: We do not need to

make a long incision in appendicitis cases that are operated upon at the outset of the inflammation, or in interval cases, as a rule; and there will be no hernias and no permanent scars if the surgeon will accept as standard the author's abdominal incision, which is one inch and a half in length, the divided structures of the abdominal wall being united separately with fine catgut afterwards. The author buries the stump of the appendix with Lembert sutures. His abdominal scar disappears entirely, so that at the end of a few months it cannot be seen. His death-rate has been nothing at all in cases without pus, and physicians upon whom he depended for cases were now ashamed to have him find pus in the cases to which they called him. He did not know just where to look for danger in any of the cases operated upon at the time of his choice, but called the attention of members of the Society to one danger in the use of carbonate of sodium for reversing peristalsis of the bowel. A note was at present going the rounds of the press to the effect that carbonate of sodium was useful in reversing peristalsis, but the author, in experimenting with rabbits, accidentally discovered that carbonate of sodium, on touching the ileum, regularly produced intussusception in less than forty-five seconds. The mechanism of the intussusception consisted in spasm of a belt of circular muscular fibres of the ileum, and this portion was then quickly invaginated by the peristaltic action of the longitudinal muscular fibres. The author now uses chloride of sodium for reversing peristalsis in all of his operations.

He stated that there was strong opposition to his plan of removing an infected appendix just as soon as it was discovered; but this opposition must fade away as soon as physicians generally could benefit from his experience, which was to the effect that appendicitis was an infectious, exudative inflammation, which did not disappear on disappearance of the symptoms. He had removed a large number of appendices from patients who felt perfectly well, but who could not obtain life insurance, or who feared recurrence, having had a previous attack of appendicitis. In all of these cases he found destructive processes in progress. Sometimes there was slowly-progressing necrosis of the lymphoid tissue of the appendix; sometimes he had found tuberculosis or carcinoma insidiously beginning at the seat of the old inflammation; sometimes adventitious bands set snares for bowel, and he had discovered that proliferating endarteritis, which must eventually lead to gangrene of the appendix, was common in very mild chronic cases. He had

found proliferating endarteritis producing slow occlusion of the arteries of the appendix in three mild chronic cases in succession.

The author stated that surgeons were laughed at occasionally because they found normal appendices at operation for supposed appendicitis; but he did not believe that proper examination was made of the specimens. He had removed two or three appendices which were apparently perfectly normal, but the patients' symptoms all stopped after the operation; and when cultures of bacteria and microscopic sections had been made from these specimens, it was found that they had been dangerously infected. The mucosa and adenoid tissue were undergoing destruction by the colon bacillus.

The author stated that when his inch-and-a-half abdominal incision was employed in removal of infected appendices, patients left the hospital at the end of a week and a half. If an incision two inches long were made, the patient would not be ready to leave until fourteen days after the operation; and if the incision were from two and one-half to four inches long, eighteen days would be required for repair. Consequently he had adopted as standard the inch-and-a-half incision and week-and-a-half confinement plan, which left no hernia and an evanescent scar.

By operating immediately in acute cases, he did not mean on the following day, but on the following hour.

Physicians who do not accept this plan must lose a few cases that they do not expect to lose, and they must let very many patients suffer tediously and unnecessarily; but there will not be much further opposition, because physicians are only too glad to do the very best thing as soon as they have learned what it is.

The insurance companies would not insure a patient who had ever had appendicitis, and whose appendix still remained, if they were to note the character of the adventitious peritoneal bands which form in these cases, and if they observed the persistence of appendicitis and of supplementary diseases in the appendices of patients who were thought to be quite well.

#### A NEW OPERATION FOR THE TREATMENT OF CHRONIC EMPYEMA.

DELORME (*Revue de Thérapeutique Médico-Chirurgicale*, 61 année, No. 3) proposes a new operation for the treatment of chronic empyema, having for its end the freeing the lung from its adhesions and its investment of false membrane, and the placing of it in such a

condition that it may again become a useful organ.

He first makes a large opening in the chest wall by the formation of a thoracic flap, then ablates the false membrane which covers the lung and ties it in the vertebral gutter, and finally replaces the thoracic flap.

He reports a case in point. The patient, aged twenty-four years, suffered in May of last year with left pleurisy. In August of the same year he was operated on for empyema, over a pint of pus being evacuated. There remained a fistula, which discharged freely, the patient suffering from hectic. Sounding through an opening showed that there was a large cavity extending to the top of the chest and about six inches in depth. A flap was marked out from the third to the sixth rib inclusive, with its base above and to the rear. The shape of the flap resembled the three sides of a rectangle, the upper and lower lines running parallel to the ribs, the base corresponding with the anterior border of the scapula, the anterior limiting line running parallel with the sternum three fingers' breadth to the left of its border. The incision was made in these lines, and the ribs were divided in front, the intercostal arteries being picked up with hæmostats. Posteriorly, the ribs were half cut through, then broken, thus turning back the entire flap with the soft parts attached to the ribs. The parietal pleura was covered with a pseudo-membrane two-fifths of an inch in thickness, with a granular, fungous surface. The latter was removed by curetting and vigorous friction with compresses. Even then it was impossible to locate the position of the lung, the pericardium, and the heart. The stripping off of the thick investing membrane was begun from the lateral chest wall far back. As the lung was freed it readily expanded, and indeed this expansion was so great that it projected from the thoracic cavity. When the surface of the lung and the costal pleura were entirely free from false membrane, the flap was replaced by suture, no ligatures being applied to the intercostal arteries. The operation lasted one and a half hours.

The author particularly remarked the absence of congestion and of circulatory or respiratory troubles, which might have been expected from the sudden release of an entire lung from its fixed position; the immediate beneficial influence upon the cyanosis from which the patient had suffered; the absence of any notable symptoms dependent upon the very considerable pressure which was exerted upon the lung during the process of freeing it from its adhesions; the facility with which the

layers of false membrane were dissected; the normal appearance of the lung; and the absence of notable hemorrhage.

Delorme concludes with the statements that it is possible to entirely free a lung from false membrane which surrounds it, even though the operation is undertaken long after the beginning of the empyema, and that this method is applicable not only to the right, but also to the left, side, and that it is without danger, provided the liberation is begun as far back as possible. He holds that the method is more rational and more conservative than that of osteoplastic resection alone, since in case it succeeds it obliterates the cavity by means of the functional lung.

#### ACUTE INTESTINAL OBSTRUCTION; ANASTOMOSIS WITH MURPHY'S BUTTON.

CORDIER (*Journal of the American Medical Association*, vol. xxii., No. 6) reports the case of a man aged twenty-two, giving a history of previous peritonitis, who was suddenly seized with the symptoms of acute intestinal obstruction. Eleven days later there were symptoms of intestinal perforation. The temperature dropped to 96.5° F., the pulse went up to 140. Intestinal gas and fecal matter escaped as soon as the belly was opened. A hard, vascular band was found running from near the right internal inguinal opening, attached to the abdominal parietes, passing upward and inward towards the umbilicus, crossing a coil of the ileum and attaching itself to a coil of the small bowel higher up. It was at this point that perforation was found, due to the tension of the band. The rent in the bowel was sutured, the portion of gut which was strangulated in the band was released, and lateral anastomosis was done around the seat of constriction by means of a Murphy button. The peritoneum was thoroughly irrigated with hot sterilized water and was drained. The operation required thirty minutes. The patient recovered, abdominal distention being relieved by a large enema, to which was added two or three drachms of turpentine and half an ounce of glycerin. Four weeks after operation the button had not been passed.

#### THE TREATMENT OF WARTS.

KAPOSI (*Revue de Thérapeutique Médico-Chirurgicale*, 61 année, No. 3) summarizes the treatment of warts as follows: Discrete out-growths should be removed with a sharp spoon,

hemorrhage being arrested either by pressure or by cauterization of the bleeding surface. When the warts are very numerous, their removal by fuming nitric acid or tincture of thuya is to be preferred. Condylomata should be sprinkled with resorcin or salicylic acid, or should have applied to them plasters containing ten to twenty per cent. of these substances. An excellent application is as follows:

R Flowers of sulphur, 20 parts;  
Glycerin, 50 parts;  
Pure acetic acid, 10 parts. M.

This is painted on daily for several days. Under its application the growth dries up and drops off.

Keratoses of the palms or feet is treated by plasters of resorcin or salicylic acid.

#### THE INFLUENCE OF DIABETES ON SURGICAL INTERVENTION.

REYNIER (*Revue de Thérapeutique Médico-Chirurgicale*, 61 année, No. 3) calls attention to the different reactive powers shown by the tissues of diabetics to traumatism, infection, or surgical intervention. In some cases operation is as safe as in the ordinary healthy being, in others the least surgical interference results fatally. Diabetes associated with extensive atheroma is, according to the author, the safest form of the disease for the surgeon. The nervous or pancreatic form of diabetes is the most dangerous form. Also, as diabetes progresses tissue resistance is lessened, hence intervention is safer in the early period of the disease than when it is well developed. Only absolutely necessary intervention should be practised when the disease has reached such a stage that the reflexes are abolished. Any form of irritation may precipitate sphacelus, which is practically always threatening. Carbolic acid and all dressings which are in the least irritating are contraindicated.

When gangrene has developed without inflammation, absorbing powders, such as salicylate of bismuth and iodoform, are useful.

There are two classes of surgical affections which may be subject to operation in diabetics who still preserve their reflexes. These are neoplasms and spontaneous infectious lesions. The removal of neoplasms should be avoided unless it is absolutely necessary. Most rigorous asepsis is required, as the slightest germ infection will certainly be followed by disastrous results. Antisepsis is contraindicated because of the irritative qualities of the drugs employed. Even should the reflexes be preserved,

operation should not be undertaken if the amount of sugar is more than fifteen or twenty grammes daily. Preceding operation a rigorous course of general treatment should be instituted.

In spontaneously infected cases three indications should be met: to avoid irritation, to limit infection, and to provide for free drainage, since there is practically not sufficient reactive power for absorption. This implies prompt incision of suppurating foci; the thermo-cautery or galvano-cautery may be employed, since thus opening of the vessels is avoided and hence the danger of propagation of infection is lessened. Generally the less the wound is interfered with the better for the patient.

Of forty diabetics operated on by the reporter, fifteen died from gangrene or allied conditions. Of these fifteen cases, two only preserved their reflexes at the time of operation. Of the remaining twenty-five cases, three died and twenty-two recovered.

#### TREATMENT OF ULCERS OF THE LEG.

FRANK (*Journal of the American Medical Association*, vol. xxii., No. 6) treats ambulant patients suffering from chronic ulcer of the leg according to Unna's method, as follows: The granulations are first thoroughly cleansed, then treated, according to indications, either with nitrate of silver if there should be hypertrophic granulation, or iodoform if the surface is putrid, torpid, and lacking in vitality. The leg is then washed and shaved, and a moderately thick layer of warm gelatin is applied up to the limits of the ulcer by means of an ordinary brush. This gelatin is thus prepared:

R Oxide of zinc, 30 parts;  
White gelatin, 40 parts;  
Glycerin, 50 parts;  
Water, 90 parts.

A small patch of gauze is added as a covering to the sore, and a gauze roller, beginning at the toes, is wound firmly around the limb. When a firmer dressing is required,—that is, when it is necessary for it to remain for a long time,—the layer of gauze is covered with another layer of gelatin, and the bandage is continued over this from above downward. The gelatin is then allowed to cool and become dry, whereupon the patient can be dismissed without further precautions. When the discharge is abundant, this dressing must be repeated at intervals of three days. As discharge

diminishes, the dressing may be allowed to remain on eight days or longer. It is perfectly protective, exerts even compression on the leg because of the elasticity of the gelatin, and prevents the discharge from coming in contact with healthy skin.

The author highly lauds resorcin as an agent potent to produce new epithelial formation. It is applied, as soon as healthy granulations make their appearance, in the form of a ten-per-cent. plaster. When the ulcer is unusually callous this dressing will not be efficient, the ordinary adhesive plaster straps and flannel bandage then being indicated. Diachylon plaster is preferred to the ordinary adhesive plaster, and oleum fagi is painted over the thickened surroundings of the granulations.

#### HEMORRHAGIC EMISSIONS.

LYDSTON (*Journal of Cutaneous and Genito-Urinary Diseases*, vol. xii., No. 137) reports five cases of hemorrhagic emissions. In two of them the blood was probably derived from an acutely congested and inflamed mucous membrane lying just behind a stricture. Orgasm, by adding to this congestion, caused rupture of smaller vessels. The third case was an instance of prolonged excitement producing such engorgement of the sexual apparatus that, even though there was no evidence of disease, bleeding occurred during orgasm. In this instance directions as to sexual hygiene, administration of ergot and bromides, and occasional introduction of a cold steel sound brought about a cure. The last two cases were representative cases of vesiculitis and posterior urethritis. These were treated by careful attention to hygiene, irrigation of the rectum with hot water, internal administration of ergot and the bromides, and mild astringent lotions applied to the posterior urethra by means of a short urethral nozzle.

#### THE ABSORPTION AND ELIMINATION OF MERCURY WHEN ADMINISTERED BY INUNCTIONS.

WELANDER (*Revue de Thérapeutique Médico-Chirurgicale*, 61 année, No. 3), basing his conclusions upon the fundamental belief that the quantity of mercury eliminated by the urine bears a certain proportion to that taken into the system, holds that the absorption of mercury is influenced not at all by the excipient used in forming the ointment, though personally he prefers lanolin. Ointments which are rubbed in most rapidly are those containing 1

part of mercury and 2 parts of fat. The method of rubbing, whether by the naked hand, the gloved hand, or the glass rod, does not materially influence the amount of drug absorbed, nor do baths exert any direct influence, acting simply in cleansing the skin, thus augmenting its absorbing power. It is immaterial whether the ointment be rubbed in immediately after the bath or several hours afterwards. The amount of mercury absorbed after simple smearing on of the ointment is greater than that absorbed as the result of friction alone.

Welanders holds that when inunctions are used a large amount of ointment should be employed, so that a part can be absorbed during the rubbing and the remainder can be left on the skin under a bandage. He recommends that, in place of rubbing, ointment should be simply smeared on the surface in the evening; after this the patient should be kept in bed for from ten to fourteen hours in a warm room.

#### TREATMENT OF CHANCRE WITH PEROXIDE OF HYDROGEN.

WORSTER (*Journal of Cutaneous and Genito-Urinary Diseases*, vol. xii., No. 137) calls attention to the rapidity with which chancres heal under somewhat prolonged spraying with peroxide of hydrogen, full strength, the vapor of which is projected against the lesion with a cylinder pressure of sixty pounds. Three cases are reported which seemed to corroborate the author's claim for this method. It is one which has long since been recognized as the most efficient means of applying antiseptic solutions, and indeed simple sprays of water alone exert a surprising resolvent effect upon both acute and chronic phlegmons, some of the French observers having claimed for this method, when carbolic-acid solutions are used, absolutely abortive effects in the treatment of carbuncles or boils.

#### TREATMENT OF OLD LUXATIONS OF THE SHOULDER.

THIERY (*La Tribune Médicale*, 27 année, 2e sér., No. 4) presented a patient forty-eight years of age, suffering from luxation of the shoulder for three months. The luxation was of the subcoracoid variety. In case of the shoulder, Thiery holds that the case must be considered old after the lapse of a month. As to the question of irreducibility, Nélaton's teaching is followed, that the common cause of this is a button-hole tear in the capsule without detachment of the latter from its points of

bony insertion; hence the posterior portion of the capsule lies across the glenoid cavity, practically filling this shallow depression. As the luxation persists, the glenoid cavity becomes less marked. Also it is quite possible for the head of the humerus to pass through a button-hole opening of the coraco-brachialis, or it may pass quite under this muscle. In one case seen by the author the head of the bone had perforated the pectoral muscle and become subcutaneous. Reduction by ordinary means was quite impossible, and before the bone could be replaced open incision was required, although the injury was only of eight days' standing. In this instance the pectoral muscle offered no obstacle to reduction, the coraco-brachialis being the muscle at fault.

Adhesions quickly take place between the capsule and joint surface after luxation, thus rendering return by manipulation progressively more difficult. Moreover, the head of the bone contracts adhesions in its new position as a part of nature's process in forming an artificial joint. The author advises always, in case of old luxations, to first try the proceeding of Kocher before having recourse to other methods. This can be attempted without anæsthesia. In the event of failure, ether is administered, and counter-extension and coaptation attempted. In case of failure in efforts not persisted in for an undue length of time, the question of operation will depend upon the amount of motion which the surgeon is able to procure by his manipulation. If this is sufficient to qualify the patient for his work, and if, moreover, there has been no complaint of great and disabling pain, it is well to advise against open operation.

In the case presented, as the movements were sufficient and as the patient was not seriously incommoded, surgical intervention was rejected.

In discussing what should be done in operative cases, subcutaneous division of fibrinous bands was absolutely rejected, as was manual osteoclasis, with the idea of forming an artificial joint. The method of operation in these cases should be opening the articulation by a free incision, preparing the glenoid cavity, freeing the head of the bone and placing it in its normal position. If, when this operation is attempted, the head of the bone is so firmly fixed in its abnormal position that it is impossible to mobilize it, resection of the humerus is indicated, saving, however, as much of the shaft as possible.\*

\* Kocher's method consists in placing the elbow at right angle and pressing it close against the side. The

*SUPRAPUBIC CYSTOTOMY COMPLICATED  
BY ADHESION OF THE PERITO-  
NEUM TO THE SYMPHYSIS.*

ROLLET (*Lyon Médical*, No. 3, 1894), after an historical review of the operation of suprapubic cystotomy, reports a case which was complicated by a peculiar anatomical arrangement of the parts. Tillaux and others hold that this operation is free from danger of wounding the peritoneum, since this membrane is lifted out of reach by the distended bladder, though Féré calls attention to the fact that post-mortem examination of a certain number of old men suffering from double inguinal hernia showed the peritoneal cul-de-sac in front of the bladder resting in contact with the pubis. Petersen also states that there are two cases on record in which the peritoneum was adherent to the pubis, and Pitha records a similar case. Polaillon, in performing suprapubic cystotomy for the removal of a large calculus, found that, in spite of previous distention of the bladder, the peritoneum was in the line of his incision. Subsequent post-mortem examination showed that in this case, too, the vesico-abdominal cul-de-sac of the peritoneum descended as far as the pubis.

The case reported is of a man sixty-nine years old, suffering from retention. No instrument could be passed through the urethra; the bladder was distended until it almost reached the level of the umbilicus. Puncture was made above the pubis with a trocar, the canula being allowed to remain in place. About two quarts of urine were evacuated. Two days later, on account of fever and some signs of wound infection, suprapubic cystotomy was performed, including the trocar wound in the line of incision. After the superficial cut the finger was introduced along the grayish channel of the trocar wound, tearing a membrane, which was found to be peritoneum; the wound thus formed allowed a loop of gut to escape; hence the trocar had entered the peritoneal cavity before puncturing the bladder. The peritoneal adhesions to the symphysis were freed; the peritoneum was closed by silk. The bladder

humerus is then carried in outward rotation as far as possible by sweeping the forearm outward. When this motion is completed, the head of the humerus should roll outward below the acromion process. Unless this change of the position of the head is noted, the further steps of this process will be useless. While the humerus is still held in extreme external rotation, the elbow is carried forward and upward as far as it is possible to push it by the continued force exerted by the surgeon's hand. The arm is then rotated inward and the elbow carried to the side of the chest. All these motions should be done slowly and deliberately.

was then punctured, and the prostate was found to have two large lateral lobes. The walls of the bladder were sutured to the borders of the parietal wound. The patient died two weeks later from uræmia.

The author holds that this lesson should teach that in every case of cystotomy, even though the bladder be greatly distended, immediately after incision of the subperitoneal fascia there should be a careful search made with the finger for the peritoneal cul-de-sac, bearing in mind the possibility of its adherence to the symphysis. When these adhesions are present they are readily torn by the finger and the peritoneum is stripped up, exposing the anterior bladder wall.

Poncet has shown that suprapubic puncture for the relief of distention of the bladder is a dangerous procedure, since from it abscess may result or infection of the prevesical cellular tissue or urinary infiltration. This case proves that peritonitis can also be caused by this procedure, and had the canula been withdrawn after two or three days it is more than probable that a general septic peritonitis would have followed.

*EXTIRPATION OF THE SHOULDER, ES-  
PECIALLY IN REGARD TO ITS  
APPLICATION IN SARCOMA  
OF THE HUMERUS.*

NASSE (*Sammlung Klinische Vorträge*, No. 86, 1893) presented a patient with a completely healed wound fourteen days after the arm, the scapula, and part of the clavicle were removed because of sarcoma of the humerus. He states that this operation was first performed by Cuming in the beginning of the present century, and that in 1888, Adelman could collect only sixty-seven cases, including those instances in which the operation was done in two stages,—i.e., in one the arm is removed, and later on the scapula and clavicle are taken away.

The method employed consists in preliminary ligature of the third portion of the subclavian artery; corresponding to the point of ligaturing the clavicle is sawed through, the subclavian vein ligated after elevation of the arm, and the brachial plexus is divided. The ligation incision is carried in a curve over the outer portion of the clavicle, being dissected away from this bone. From the outer end of this incision the cut is carried downward to the axilla, then to the angle of the scapula. The pectoral muscles are divided and the scapula is freed from the thorax as far back as the serratus magnus. The latissimus dorsi is then cut

through and the angle of the scapula freed. But little hemorrhage follows this portion of the operation; still, all bleeding points are seized at once and the wound is covered with a gauze tampon. The shoulder is then drawn forward and the posterior cut is made, passing from the external extremity of the incision first made for the purpose of ligation of the subclavian directly backward and downward to the angle of the scapula, where it joins the first incision. The skin is dissected back, and the upper posterior borders of the scapula freed by free incision of the rhomboidei muscles. With the division of the serratus major, the separation of the arm and shoulder is completed. When this cut is made there is usually free bleeding from the branches of the transversalis coli and transversalis humeri. This is readily checked. The flaps are now trimmed up and the wound closed. The precaution should be taken in raising the flaps to include no muscle, though the flaps should be made as thick as possible. If the flaps are made too long and thin, gangrene may occur; hence any muscles which still preserve their blood-supply should be retained, provided they are not infected.

The point of this operation consists in the preliminary ligation of the subclavian artery and vein before beginning the formal operation. This, too, is the most difficult procedure. Von Bergmann has performed this operation in the last few years fourteen times; two of these cases had previously been subjected to amputation or exarticulation at the shoulder-joint. There was only one operative death among these cases. In this instance incision showed that the sarcomata had infiltrated the subclavian artery and vein and had reached the superior vena cava; hence, to avoid immediate fatal bleeding, ligature of the vena cava was required. The patient died very shortly, but in this case death could not be attributed to amputation of the shoulder. None of the other patients suffered from serious shock. Most were well in two or three weeks. Some had a discharge from the track of the drainage-tube for a longer time.

As far as the operative results are concerned, these are entirely satisfactory. When, however, this procedure is adopted for the radical cure of malignant tumor, the results are by no means so favorable. One form of sarcoma—namely, the medullary giant-cell growth—is comparatively non-malignant, and in certain cases even local exsection is followed by permanent cure. These growths spring from the medulla of the bone in the epiphyseal region and very seldom rise from the diaphyses. A

point of special importance is that they are encapsulated and grow slowly. Even when the capsule ruptures they are not prone to infiltrate. There are, however, certain malignant giant-cell sarcomas of the bone which are prone to give rise to metastasis. In the strictly encapsulated forms of sarcoma thorough removal by the knife, chisel, and curette is sufficient, the limb in this case being saved. Exceptionally there is recurrence *in loco*, but this is not the rule. Four patients are reported subjected to this local operation. In one three years passed since operation, in three over five years.

All the other forms of sarcoma exhibit decided malignancy; indeed, local removal is practically never sufficient to accomplish radical cure. Even though the limb be entirely removed, the prognosis is by no means bright. This is due to the rapid dissemination of the growth incident to the close connection of sarcoma with the blood-supply, the infection travelling particularly along the venous channels. In every patient where venous involvement had extended beyond the limits of the growth, so that it was macroscopically visible, metastasis occurred. To prevent metastasis, early diagnosis and radical operation are of course demanded. It is well known that as long as sarcoma is confined within the bone or the periosteum its growth is greatly limited, but as soon as it breaks through its capsule its increase in size is extremely rapid. The muscles are first infiltrated and then the intermuscular septa. This dissemination is rapid; hence the futility of attempting removal by a purely local operation. Even amputation often fails to prevent récidivity. Of forty amputations and exarticulations, recurrences occurred in five. Of fourteen cases of extirpation of the shoulder mentioned by Nasse, in twelve the operation was undertaken for the cure of sarcoma. One perished immediately following operation, on account of extensive disease of the vein; two perished of recurrence. In both these cases the arm had previously been amputated, and shoulder extirpation was undertaken for recurrence *in loco*. Two patients have been operated on within the last year. All these cases can be set aside in considering the question of recurrence. Of the remaining seven primary sarcomas of the humerus, four were suffering from involvement of the shoulder-muscle at the time of operation. There were two recurrences *in loco* in these cases and two deaths from metastasis. In three cases the shoulder-muscles were healthy; récidivity occurred in none of these. They were all large tumors. In one instance

the sarcoma had involved not only the bone and soft parts, but had extensively infiltrated the veins. This patient perished of metastasis. Of the two remaining cases, both exhibited muscular infiltration of the arm. In spite of this, both are living, one five and a third years from the operation, the other three and a third years following surgical interference. Nasse strongly urges this radical operation whenever the sarcoma of the humerus has ceased to be strictly encapsulated, and brings in support of his argument what he states are the much more favorable results of operation in mammary cancer when, in accordance with modern methods, not only all the tumor is removed, but the axilla is cleared out and part or whole of the pectoral muscle removed also. This radical operation he would not advise in cases of sarcoma of the forearm.

---

*ENTERECTOMY; END-TO-END ANASTOMOSIS; CHOLECYSTENTEROSTOMY WITH MURPHY'S BUTTON.*

ROGERS (*Medical Record*, vol. xlv. No. 4) reports two cases of abdominal surgery. In the first the patient gave a history of inguinal hernia which was suddenly brought down by a jar. This was apparently reduced by taxis, though the patient still continued to complain of pain. There was slight induration at the site of the internal ring, but apparently within the abdominal cavity. For two days purgatives and enemata failed to act on the bowels; the abdomen gradually became distended and tympanitic. At the end of this period there was marked tenderness over the umbilicus, down to the inguinal canal on the right side, and faecal vomiting. No hernia could be felt in the inguinal canal, though just above Poupart's ligament, and just under the internal ring, there remained a small induration indistinctly felt on account of the distention of the abdomen. The conclusion was that the hernia had either been reduced in its sac, or else that both had been pressed up within the inguinal canal. An incision of three inches was made over the site of the appendix. At least a pint of blood-stained fluid escaped from the peritoneal cavity. Eight inches of intestine were drawn; the seat of constriction was at the internal ring. The constricted gut was brought through the abdominal wound to the outer surface of the abdomen. It was so congested that at each end of the eight inches, where the encircling band had constricted it, the peritoneum had given way and gangrene was imminent. Ten inches of gut were resected and

end-to-end approximation was accomplished by means of Murphy's button. The abdomen was drained and closed. Fifteen grains of calomel were given the night of operation, ten more were administered the next day, and by means of oft-repeated large enemata the intestinal canal was thoroughly emptied of all gas and faecal matter at the end of sixty hours. Convalescence was uninterrupted. Drainage was removed on the third day; the button was passed on the seventh day.

The second case was suffering from distended gall-bladder with enlargement of the liver. An incision was made two and a half inches below the anterior extremity of the ninth rib, extending backward three inches; the fundus of the gall-bladder was brought into the incision, was opened, and from it escaped fourteen ounces of bile. The patient was so shocked that operation was completed as rapidly as possible, the gall-bladder being sutured to the anterior wall of the abdomen. At the end of three weeks the swelling of the liver had subsided and the patient was in good general condition. Six weeks from the first operation the patient was again anaesthetized and another exploration was made for the obstruction of the common duct, two enlargements, apparently calculous, being found. The condition was not such as to justify efforts at removal of these stones, so that cholecystenterostomy was performed by means of the Murphy button. This button came away from the fistula in the abdomen on the seventh day, and there was much trouble in keeping food from escaping by way of the gall-bladder. Most of the bile passed into the bowel. The patient returned to his home at the end of four weeks, after which time he began to gain in weight. Three months after operation he was taken with diarrhoea which, soon becoming dysenteric, caused death on the third day.

---

*VENTRAL HERNIA FOLLOWING LAPAROTOMY.*

MCARDLE (*Medical Press and Circular*, January 24, 1894) holds that there are many causes which interfere with prompt and thorough healing of a laparotomy wound. He places these in order of importance thus:

1. Failure to engage the different layers of this stratum sufficiently in the sutures.
2. Interposition of contused peritoneum.
3. Hæmatoma not becoming soundly organized.
4. Suppuration from inherent or extrinsic causes.

The remedy for this is to suture the abdomen in all laparotomies, as we do in all cavities in which blood or serum could collect, and to avoid contusing the peritoneum by using catch forceps, such as suggested, with sharp points.

The steps of the operation, as McArdle believes it should be conducted, are: Incision of the skin on one side; isolation of the neck of the sac along this side, then undermining not only the skin, but all the tissues on the other side of the neck, making it possible to cut cleanly through everything down to the neck of the sac with a strong scissors with long handles. This done, and being satisfied by opening the sac that no omentum or bowel remains in it, a Hagedorn's needle is carried round in the subperitoneal tissues, like a purse-string. This being drawn and tied, and numerous sutures carried with the same needle through the aponeurosis, close the wound over the mouth of the purse after cutting the ligature. Skin sutures passing deeply and taking up the floor of the wound are now applied and knotted, and the operation thus completed.

---

*TREATMENT OF INFANTILE HERNIA  
OF THE INGUINAL TYPE IN  
THE MALE.*

MANLEY (*Journal of the American Medical Association*, vol. xxi., No. 25) holds that treatment of infantile hernia of the inguinal type, in the absence of complications, should be on tentative lines. It is only in exceptional and unusual cases that the question of operation will arise. This holds true of the class which is seen in the sucking infant before walking begins. The treatment should have reference to diet, clothing, rest, support or pressure, removal of such causes as cause straining, and radical operation. The clothing should not include the tight encircling band so commonly applied over the lower thorax and entire abdomen. This renders spontaneous cure of the hernia impossible. Rest is one of the most potent agencies in accomplishing cure in every species of hernia and in every stage of life. The herniated infant should be kept in a lying and sitting position as long as possible. A small, painless hernia which shows no tendency to enlarge, will do better by entire non-interference than by the misdirected application of pressure. In the simple cases, a simple bandage support will probably do no harm. Before applying this, the descent of the testis

must be assured and the possibility of the hernia being a simple cyst must be excluded. For support, the hank truss, made of a couple of skeins of worsted, or the simple pad and spica bandage, amply suffice. The general use of the spring truss in infantile hernia is a bad practice. Its adoption is to be prohibited except in those cases in which the medical attendant is permitted to keep the case under constant observation. Trusses with a strong spring do incalculable harm. By their pressure they often not only prevent the testis from fully descending, but they likewise induce adhesions of it with other parts. Simple reducible hernia they render irreducible in many cases; and in many, too, by their constant pressure, they induce atrophy over the rings which they are supposed to strengthen. When the child takes to his feet, the truss plays an important rôle. The infantile hernias which require operation are, (1) those in which there is a marked tendency to increase in volume, (2) those which are attended with severe pain, and (3) those in which there are extensive adhesions between the testis and viscera, and there are no possible prospects of reduction or cure without radical methods. The technique of operation is practically the same for the young and the adult. Some sort of support should be worn for a year after operation.

---

*A SPECIAL METHOD OF APPLYING THE  
THERMO-CAUTERY IN THE TREAT-  
MENT OF CERTAIN CASES OF  
LUPUS VULGARIS.*

For years past reports as to the efficacy of the thermo-cautery in the treatment of lupus have occasionally found their way into print, but no details have been given as to how or when this valuable instrument should be employed.

STOPFORD (*Liverpool Medico-Chirurgical Journal*, No. 26, 1894) reports in detail two interesting cases treated by the thermo-cautery with markedly beneficial results. The first case was that of a woman, aged twenty-eight, who had lupus of six years' standing, which originated in a wound in the lobule of the right ear. The disease involved the right ear, the whole of the right cheek, extending to within an inch of the outer canthus and the nasal and oral orifices, the integument over the mastoid process and the scalp for an inch above it, while inferiorly it swept under the jaw from a point three inches below the situation of the lobule of

the ear to the larynx. The helix and lobule were completely destroyed. Previous to coming under the writer's care she had undergone scraping and the use of the solid stick of caustic potash, without arresting the disease. By her own desire she was inoculated with Koch's tuberculin during August and September, 1891, which treatment had no perceptible effect beyond causing a little desquamation. Considerable melting down and subsequent improvement took place in the scar tissue, but the tuberculin had the effect, without doubt, of causing a rapid increase in the patch; the spreading of the margin and development of nodules at the periphery next the median line of the face was most noticeable.

In October the patient came into the hospital to undergo treatment with the cautery, with a sore on her head caused, as she stated, by an iron pan weighing eight pounds falling upon her during the time she was at home undergoing inoculations. Examination revealed a lupoid patch situated to the left of the anterior fontanelle, measuring one and a half inches by one inch in diameter. This was freely excised down to the periosteum of the skull, and the margins of the wound lightly touched with the thermo-cautery knife. The original disease on the face was firmly rubbed with a piece of lint soaked in a solution of liq. potass., 1 to 3, in order to remove any adherent crusts or scales and expose the superficial extent of the disease. The whole involved surface was very carefully gone over with a spoon, and when bleeding had almost ceased a succession of punctures, each a quarter of an inch deep, were made with the needle-cautery. These were so close as to form a continuous line around the edge of the advancing margin; and lest this should prove ineffectual in arresting the disease, a second series of punctures in the healthy skin, in like manner, were made outside the first, at a distance of a third of an inch; then with the button-cautery at nearly white heat the whole was firmly and slowly stroked again and again until a hard, brown, leathery-looking eschar resulted. A carbolized oil dressing was applied twice daily until the sloughs separated, and in four or five days a clean and healthy but freely-suppurating wound remained. After this radical treatment many lupoid nodules still remained, but gradually disappeared under the influence of a weak mercurial paste rubbed in twice daily.

The second case was that of a child, aged thirteen. The disease occupied the whole left cheek, covering much the same extent as in

the first case. Owing to the extreme vascularity and thickness of the lupus, Stopford determined to treat the disease as a *nævus*, by multiple puncturings an eighth of an inch deep with the cautery-needle. These were continued until the whole patch assumed a reddish-gray appearance. The margin also was surrounded by a cordon of punctures. Free sloughing resulted. When the surface healed the lupus was subjected to multiple linear scarification on two separate occasions. Following this treatment, all the lupus, except a few nodules, disappeared without further applications, and the cicatrix became perfectly white and presented no hypertrophy. It is interesting to note that no nodules developed outside the ring of punctures, though a few appeared on the forehead at a little distance from the excised patch in the first case.

During the past two years the writer has operated on twenty-odd cases with the thermo-cautery. Some have been treated with the button, others with the knife, and others, again, with the cautery-needle; some, again, with a combination of all three. He divides the modes of treating these troublesome cases into two classes: the first, aiming at removal and destruction of the morbid process by scraping, and subsequent cauterization by chemical agents; the second, by the thermo-cautery alone or in conjunction with other measures. It not only destroys the disease, but causes any remaining morbid tissue to disappear by toning up and reducing vascularity of the part diseased.

His routine method, with slight modifications, as warranted by experience in individual cases, is to wash the diseased area with a solution of potash, varying the strength according to the thickness of the horny layer; then it is thoroughly and carefully scraped. Should much hemorrhage occur, the use of the cautery is postponed until next day. The choice of the cautery-button or needle depends upon the depth and vascularity of the disease. The needle puncture is best to isolate the lupus patch from its surroundings. He uses the button cautery as hot as possible, so that it chars the superficial tissues immediately it comes in contact, preventing too great destruction of subjacent tissues, while permitting sufficient heat to pass through to partly obliterate the papillary plexus. When the slough separates and the wound is healed, the cicatrix is a pale pink color, ultimately becoming quite white. Should nodules appear in the scar, they are immediately bored out. It is obvious that surface cauterization will fail in all cases of lupus in-

filtrating subcutaneous tissue; for these the multiple puncture with the cautery-needle enables piercing of the deeper horizontal vessels, thus sealing the channel by which the infective process is nourished and its products carried to the adjacent parts.

*CEREBRAL TUMOR DIAGNOSED BY  
FOCAL SYMPTOMS, WITH OPERA-  
TION AND SUCCESSFUL  
REMOVAL.*

STEELE (*Journal of the American Medical Association*, vol. xxii., No. 4) reports the case of a Swede, fifty-one years old, male, eldest of nine children, being the father of six children himself, a laborer, on whom he successfully operated for cerebral tumor.

The toilet of the operating field was thoroughly made the previous day, the head having been shaved and cleaned and a wet 1 to 2000 bichloride dressing having been applied, to be worn until time of operation.

After the patient was thoroughly under chloroform, a small, solid, cylindrical rubber band was passed around the head to render bloodless the field of operation in the scalp. Four stitches were introduced equidistant apart, binding the rubber constrictor to the scalp so as to prevent slipping. Owing to the extent of the symptoms, showing that the convolutions of the upper half on either side of the Rolandic fissure were involved, the nicety of delicate cerebral localization technique was dispensed with, and a horseshoe shaped flap of three inches width was turned down and fixed with one stitch to the integument beneath, to keep it out of the way of the operator. A large button of bone was then removed, and the opening enlarged by the rongeur to a size corresponding to nearly that of the scalp flap, a little over three inches in diameter, and heart-shaped. Palpation through the meninges showed great resistance over the region corresponding to an inch each side over the upper third of the Rolandic fissure. Below this region the resistance was normal. On opening through the meninges, there was found absence of pulsation over the region corresponding to the part offering great resistance to palpation, and slight pulsation below that region.

Faradization with a double-brain electrode over the dense tissue was followed by no muscular response, but at the lower margin of this tissue and on down the Rolandic marginal convolutions there was responsive contraction

of arm muscles. Macroscopically, the dense tissue presented a yellowish color and bulged into the wound. On digital exploration, a tumor of considerable dimensions was found extending downward into the brain and readily separable from it, a few slight adhesions of the tumor capsule alone offering any barrier to removal. After outlining the free borders of the growth, a firm pedicle was found attached to the skull or falx cerebri at the region of the superior longitudinal sinus. The tumor was shelled out quite readily with the fingers, leaving the firmer portion, the pedicle, which was removed with a strong curette, after cutting away the skull with the rongeur forceps. A large rent in the superior longitudinal sinus was necessarily made on removing the pedicle, which necessitated firm packing of the whole intracranial wound. This readily controlled the hemorrhage, which was enormous for a few seconds; but it prevented the satisfactory closure of the wound with the return of the bone chips. The regular antiseptic dressing was applied, and was not disturbed for three days, when the bulk of the gauze dressing was removed, leaving only one small piece over the rent into the sinus. At the second dressing, four days later, the remaining piece of gauze was removed.

Slight constitutional disturbances followed the operation; temperature, 101° F.; operation fever for thirty-six hours, followed by a decline to normal on third day. There was complete motor paralysis of the arm and leg for twenty-four hours following the operation, at the end of which time slight motion returned to the leg, and nineteen days later some motion was observed in the arm. Slight but steady improvement has occurred since that time. The patient first noted sensation in the shoulder muscles, the next day he could move the arm, on the third day he could draw up the forearm, and now he has good control of the whole arm except the fingers, in which he has no power and but little sensation. He makes some new movement or exercises some muscle each day. He is now able to sit up and walks a little.

The packing prevented the accurate suturing of the scalp; there was an opening of perhaps two inches through which the ends of the strips of gauze were drawn out. At the end of a week these edges were freshened and resutured. There is at the time of above report a small opening half an inch through, in which a minute strip of gauze is kept for capillary drainage. Granulation tissue covers the wound. The tumor was an endothelial fibro-sarcoma.

*LOTION FOR CONJUNCTIVITIS.*

## Reviews.

---

THE NATIONAL DISPENSATORY, CONTAINING THE NATURAL HISTORY, CHEMISTRY, PHARMACY, ACTIONS, AND USES OF MEDICINE, INCLUDING THOSE RECOGNIZED IN THE PHARMACOPŒIAS OF THE UNITED STATES, GREAT BRITAIN, AND GERMANY, WITH NUMEROUS REFERENCES TO THE FRENCH CODEX. By Alfred Stillé, M.D., LL.D., John M. Maisch, Ph.D., Charles Caspari, Jr., Ph.G., Henry C. Maisch, Ph.G., Ph.D. Fifth edition, enlarged and revised in accordance with Seventh Decennial Revision of the United States Pharmacopœia. With three hundred and twenty illustrations.

Philadelphia: Lea Brothers & Co., 1894.

The appearance of the fifth edition of the National Dispensatory so soon after the recent revision of the United States Pharmacopœia will be welcomed by the great number of physicians and pharmacists who in previous years have been subscribers to this valuable encyclopædia of pharmacy and medicine.

The late Professor John M. Maisch could not have reared to himself a more lasting monument in evidence of his great learning and energy than this work, to which he, in connection with Dr. Stillé, contributed so much.

It is hardly necessary for the reviewer to mention the fact that the scope of the work is very broad, including the description, chemistry, process for manufacture or collection, test as to purity, symptoms and treatment of poisoning, uses and action, convenient methods of administration, incompatibilities, etc., of all substances used in medicines; in fact, the scope of such a work is unlimited as to the discussion of drugs and chemicals.

In carefully reviewing the work one is struck by two facts,—first, that the history and descriptions of drugs and chemicals is by far the most complete of any of its parts, and second, that the treatment of poisoning is its weakest point. As an instance of this last-mentioned fact is to be observed, that among the substances recommended in the treatment of carbolic-acid-poisoning is oil. The more recent teaching upon this subject is that oil increases

the absorption of carbolic acid, and is therefore not to be used in cases of poisoning from this substance. The yellow ferrocyanide of potassium is not mentioned in poisoning from sulphate of copper, nor permanagate of potassium in acute poisoning from phosphorus. This is considered an oversight, as these are generally taught to be the most reliable antidotes for these poisons. We are told that in opium-poisoning the *pupils* are to be taken as one of the guides as to the quantity of atropine to be administered, and *vice versa* in cases of belladonna-poisoning in which morphine is used as a physiological antidote. Inasmuch as it has been demonstrated that opium contracts the pupils by a centric action, and that belladonna dilates them by peripheral action, it is considered unsafe to be guided by the pupils when administering these antidotes.

The authors fail to give the treatment for poisonings as fully as a work of this kind should. This the reviewer considers a serious shortcoming, as a dispensatory is the only guide upon which druggists rely when called upon to treat such an emergency case, and it is a well-known fact that many cases of poisoning are first seen by them, and they should be supplied with the most specific directions for applying intelligent treatment while the physician is being summoned.

The official preparations are, of course, directed to be made according to the latest Pharmacopœia, and as a matter of convenience the apothecary weights and measures are given, as well as those of the metric system. In the appendix there is a valuable table of comparative weights and measures between those of the apothecary and metric system, and also a condensed list of the official substances and preparations made from them.

In the preface the authors call our special attention to the therapeutic index which is to be found in the appendix. The object of such an index is, of course, to furnish the prescriber with a ready list of drugs to be used in the treatment of certain diseases. The value of this index is somewhat lessened by the use of such indefinite terms as "Diseases of the Skin," under which are mentioned more than one hundred and fifty remedies without specifying in what disease of the skin the remedy is to be used. Similar headings are "Diseases of the Eye," "Diseases of the Ear," and "Nervous Diseases." Upon the whole, the reviewer does not consider the therapeutic index a strong feature of this otherwise very accurate and valuable work.

The book is recommended most highly as a book of reference for the physician and as invaluable to the druggist in his everyday work, and it is far from the reviewer's intention to detract from its great value in mentioning what he considers the above minor defects.

The index is accurate and complete and the type and paper of the first quality.

E. Q. T.

THE MODERN CLIMATIC TREATMENT OF INVALIDS WITH PULMONARY CONSUMPTION IN SOUTHERN CALIFORNIA. By P. C. Remondino, M.D.

Detroit: George S. Davis, 1893.

Dr. Remondino is noted for the wide scope of the subjects which he has treated with his pen, and he has presented us with a little book which will prove particularly valuable to those who find it necessary to seek the delightful climate of which he writes. He gives minute directions as to the conduct of their lives, and lets the subject of medicine itself alone. As he says in his preface, many of the facts that he states are reiterated for the purpose of impressing on the reader those points which are absolutely essential to the climatic treatment of phthisis. The book costs but twenty-five cents, and the physician may with confidence obtain it and distribute it among those patients whom he has directed to seek relief in a milder climate than can be found in most portions of the United States.

A CLINICAL TEXT-BOOK OF MEDICAL DIAGNOSIS FOR PHYSICIANS AND STUDENTS, BASED ON THE MOST RECENT METHODS OF EXAMINATION. By Oswald Vierordt, M.D. Authorized translation, with additions by Francis H. Stuart, A.M., M.D. Third revised edition. Illustrated.

Philadelphia: W. B. Saunders, 1894.

This book, which is a type of the best German medical literature, has had a great success in its native land and a still greater one in this country, considering that its author is not an American. It treats of the subject of physical diagnosis from quite a different point of view from that generally followed by English-speaking writers, as, for example, Da Costa. The method which it follows makes it more valuable to the graduate in medicine than to the student of the art of healing. It is a work which no teacher of medicine should be without, and will doubtless continue to be, under the able editorship of Dr. Stuart, one of the most popular of text-books. It can certainly be heartily recommended to those who wish a reference-book on medical diagnosis.

PRACTICAL TREATISE ON NERVOUS EXHAUSTION. By George M. Beard, A.M., M.D. Edited with notes and additions by A. D. Rockwell, A.M., M.D. Third edition.

New York: E. B. Treat, 1894.

This book, which has already become a standard description of the state of the nervous system, of which it treats, has in its last two editions been kept up to the front rank by the touch of Dr. Rockwell. As he points out in the preface to the third edition, neurasthenia affords to the profession a convenient refuge when perplexed, and we fear that in many instances the careless physician is apt to give this name to a complex of symptoms without searching as deeply for the cause of the patient's complaint as would be wise. Notwithstanding the many advances which have been made in the study of this functional nervous condition, the book remains, perhaps, the best exposition of the subject in the English language, and is heartily to be recommended to those who are interested in the class of patients suffering from this annoying and serious state.

MEDICAL PRACTITIONERS' LIBRARY. TREATMENT OF THE DISEASES OF THE STOMACH AND INTESTINES. By A. Mathieu, Physician to the Paris Hospitals. 8vo, 285 pages. Parchment muslin, price, \$2.50; flexible leather, gilt top, price, \$3.25.

New York: William Wood & Co., 1894.

Many of the readers of the THERAPEUTIC GAZETTE are acquainted with the exceedingly able monograph upon "Diseases of the Stomach," by Ewald, which has been published in England by the New Sydenham Society and in America by D. Appleton & Co. The book which we now have under review is one which is smaller in its physical dimensions, and undertakes to deal not only with diseases of the stomach, but also with diseases involving the alimentary canal below the pylorus. It is more superficially written than is the German work, but should be in the hands of every physician who is forced (and who of us are not?) to treat cases of gastric and intestinal disturbance. The value of the book is increased to a great extent by the large number of foot-notes giving references to current literature, and while the work is distinctly Gallic in the method in which it is developed and the symptoms are treated, it proves to be a valuable addition to the literature of this important portion of medical practice.

OPERATIVE SURGERY. By T. H. Kocher, M.D. With one hundred and sixty-three illustrations.

New York: William Wood & Co., 1894.

This book, copyrighted in America, may be taken as indexing the most recent and popular

operative methods employed by the German surgeons. As such it is of special interest to the large class of American readers who depend for their knowledge of German methods upon the abstracts which appear in most of our current journals. In the introduction the author states that he has recommended only those methods which he has tried and proved by many years' clinical experience, and claims that the value of his contribution lies in having given simple rules for reliable and conservative surgical manipulations in every part of the body.

He advises continuous suture in closing wounds, the needle being passed alternately deeply and superficially. In the use of cocaine he teaches that several syringefuls of a one-per-cent. solution may be administered without fear, and he advises mixing cocaine in a five-per-cent. solution of carbolic acid, a method which has not met with popular favor. Ether is given the preference as a general anæsthetic. In the chapters devoted to the treatment of wounds, the secondary suture is spoken of in high praise. Under the heading of selection of the direction of the incision, Lange's investigations are quoted, showing that when two incisions vertical to each other are made they exhibit a varying retraction of the wound margins. While one gapes widely, the edges of the other remain in contact even without artificial means. This fact he has borne in mind in planning what he calls his normal incision charts, of which a number are given. Some of these do not correspond with the incisions popular with surgeons generally, though Kocher states that, fortunately, the course of the nerves and vessels largely coincides with the direction in which the skin shows the greatest tension, so that cutaneous incisions adapted to the cleavage line are least likely unnecessarily to wound important structures.

Under the heading of special operations, those done upon the blood-vessels and nerves of the face and head are first considered, after which comes a particularly valuable section on trephining and resections. Next are considered the operations in the cervical region, those performed on the thorax including osteoplastic resection, and a very short section on operations of the lung. The opening of the spinal canal receives passing notice, and nephrotomy and nephrectomy are disposed of in a few words.

The abdominal operations and intestinal sutures are briefly described. For opening of the membranous and prostatic portion of the urethra a horseshoe incision is advised, thus allowing the rectum to be turned downward

and backward, and giving free access to the seminal vesicles. The technique of operations on the rectum and of operations on the extremities, including excisions and amputations, complete the book.

In the main the operations described are much the same as those commonly used by surgeons of this country. The book will scarcely take the place filled by Treves and Jacobson, since it is not sufficiently detailed in description, and is often not expressed with that clearness and precision which particularly characterizes works of the English authors. It is, however, a useful reference-book, and one which the surgeon should have in his library.

THE JOHNS HOPKINS HOSPITAL REPORTS. Vol. III., Nos. 7, 8, 9. Report in Gynæcology, II.

Baltimore: The Johns Hopkins Press, 1894.

These reports, contributed in the main by Howard Kelly, admirably illustrated, and with tabulations which show how minor a detail is expense in the publications of Johns Hopkins Hospital, are deserving of high praise, as showing the clinical methods of a keen, skilful expert, and as illustrating his ingenuity in combating complications and new conditions as they arise in the course of his practice. The readers of current literature are already familiar with the value of these papers, as they have appeared elsewhere.

Kelly describes his method of measuring the conjugata vera by external direct method, and, by comparison with internal measurements, shows that there is not a difference sufficiently great to be of any practical importance. The illustrations show the method at a glance.

The possible errors in diagnosis from deviations of the rectum and sigmoid flexure associated with constipation are pointed out. It is shown that such abnormal position is especially prone to be associated with fæcal stasis. A number of cases are illustrated, showing how readily the tumor incident to this condition may be mistaken for diseased conditions of the parametrium, tubes, or ovary. This article is extensively illustrated.

Forty-five cases of operation for the suspension of retroflexed uterus are reported, all recovering. The author states that there are two distinct classes of patients in which the operation is applicable,—first, in young nullipara suffering from pelvic pressure, backache, and dysmenorrhœa, in whom the retroflexion has existed for a number of years; second, in multipara in whom the retroflexion is acquired. Not only was there recovery, but in nearly all

cases very great improvement in general condition.

Mary Sherwood contributes a paper upon "Potassium Permanganate and Oxalic Acid as Germicides against the Pyogenic Cocci," showing that permanganate alone in saturated solution will not destroy the staphylococcus pyogenes aureus. With oxalic acid at a temperature of 40° to 45° C., sterilization of infected threads by an exposure of one minute to its action is accomplished.

Stavely reports a number of complications occurring in cases of abdominal section through the presence of intestinal worms. Six cases are recorded, one resulting fatally. In all reflex disturbances were most marked.

Under the head "Gynæcological Operations not involving Cœliotomy," eight hundred and thirty-eight operations were performed on six hundred and thirty-one patients. There is an elaborate tabulation of these cases.

One of the most ingenious contributions is an article upon the employment of an artificial retroposition of the uterus in covering extensive denuded areas about the pelvic floor. Six cases are cited.

Murray writes a useful article upon "Photography applied to Surgery."

Russell presents the result of his work in urinalysis in gynæcology.

Robb insists upon the importance of employing anæsthesia in the diagnosis of intrapelvic conditions, and proves his points by an analysis of some two hundred and forty cases.

Kelly describes his method of direct pressure for the resuscitation of persons from chloroform asphyxia. This seems to offer no advantages over methods already practised, and does not absolutely provide for the patulousness of the respiratory tract in so far as the mouth and nose are concerned.

One hundred cases of ovariectomy performed in women over seventy years of age are tabulated; twelve cases died. Of the three patients over eighty, all recovered. There is a tabulation of abdominal operations performed at the Gynæcological Department from March, 1890, to December, 1892. The operator calls attention to the fact that at first drainage was frequently used, but towards the last has been almost completely abandoned, the glass tube being given up altogether in favor of gauze. Over five hundred cases are recorded.

A record of deaths occurring in the Gynæcological Department is appended,—first, deaths without operation; next, deaths following gynæcological operation.

These reports are most valuable, not only

because of their direct teaching, but because they illustrate how the immense material of a large hospital can be best utilized for the general education of the profession.

A TREATISE ON HEADACHE AND NEURALGIA, INCLUDING SPINAL IRRITATION AND A DISQUISITION ON NORMAL AND MORBID SLEEP. By J. L. Corning, M.A., M.D. With an appendix upon Eye-Strain as a Cause of Headache, by David Webster, M.D. Third edition. Illustrated.

New York: E. B. Treat, 1894.

Dr. Corning's book upon headache and neuralgia treats of this manifestation of functional and organic disease in an unusually thorough manner, and the addition to its pages of the valued chapters by Dr. Webster will do much towards diffusing the knowledge of specialists concerning the reflex headaches of eye-strain. The book is devoted very much more largely to the consideration of the remedial measures to be resorted to in cases of headache and neuralgia than upon the pathology or etiology of these conditions, a fact which will doubtless recommend it highly to the general practitioner. Nothing is said, however, of the operative procedures which have become so much resorted to in cases of excessive pain of the nerves of the head, or, to speak more correctly, less than one page is devoted in chapter xxiv. to this question, and the only authorities cited are Trousseau and Nussbaum in Germany. A new edition of the work upon this subject should certainly include some references to the work of Rose and Horsley in England and Keen in America in regard to the operative treatment of this condition.

DISEASES OF THE HAIR AND SCALP. By G. T. Jackson, M.D. New edition.

New York: E. B. Treat, 1894.

We have already had occasion to refer pleasantly to the value of Dr. Jackson's book upon "Diseases of the Skin," published by Lea Brothers & Co., of Philadelphia, within the last two years. The present volume, devoted solely to the consideration of diseases of the hair and scalp, is necessarily a reproduction of some of the views expressed in his more complete work. To those who are particularly interested in the subject of which the book treats it can be heartily recommended. Not only is it laden with much valuable information, but the last forty-odd pages are devoted to a copious bibliography of the subjects under discussion. We are told in the preface that every page of the original edition has been corrected and revised, and the bibliography that we have mentioned is brought down to January, 1893.

The author has evidently used every effort to maintain his reputation as an author upon diseases of the skin.

AN AMERICAN TEXT-BOOK OF GYNÆCOLOGY, MEDICAL AND SURGICAL, FOR PRACTITIONERS AND STUDENTS. By Henry T. Byford, M.D., J. M. Baldy, M.D., Edwin B. Cragin, M.D., J. H. Etheridge, M.D., William Goodell, M.D., Howard A. Kelly, M.D., Florian Krug, M.D., E. E. Montgomery, M.D., William R. Pryor, M.D., and George M. Tuttle, M.D. Edited by J. M. Baldy, M.D. With three hundred and sixty illustrations in text and thirty-seven colored and half-tone plates.

Philadelphia: W. B. Saunders, 1894.

This work, following the plan laid down in "An American Text-Book of Surgery," has been written by ten of our leading gynæcological teachers, and edited by Baldy. At first glance the modest man is somewhat shocked at the illustrations, which to the captious critic will seem unnecessary. These, however, are all for the purpose of elucidating points made in the text, and are doubtless more impressive from the fact that the patients are exhibited *in puris naturalibus*.

The individual sections of the book are unsigned. The first eighty pages are devoted to the examination and technique of operation. Both these subjects are described with that detail which the general practitioner anxious to modernize himself in methods particularly loves.

In considering menstruation and its anomalies, it is stated that obstructive dysmenorrhœa arising from flexion should be treated by the application of an intrauterine stem pessary. In dysmenorrhœa of ovarian origin, glycerin tampons may be employed. The membranous variety is treated by dilatation and curettement. Under the treatment of sterility, artificial impregnation is given only passing notice.

The inflammatory diseases of the uterus receive the careful consideration which is merited by this important subject. For gonorrhœal endometritis, irrigations of 1 to 5000 bichloride are advised, with the insertion of an iodoform gauze drain. This treatment is repeated in twelve hours, and it is stated that when the first attempts to control the disease fail we may be certain that the infection is mixed. If there be the complication of salpingitis, the operation of curetting is necessary. The technique of curettage and of uterine tamponage is described in minute detail, and the electrical treatment of the endometrium receives due consideration.

Under the headings distortions and malpositions, the use of stem pessaries is prac-

tically turned down, curettage being given the choice in cases of ante flexion. Indeed, in this whole section the pessary is given a position of minor importance, the various operative procedures being preferred. These are specifically described.

In malignant disease of the cervix the preference is given to complete extirpation of the womb, and Byrne's method of removal by the galvano-cautery is illustrated. In considering carcinoma of the body of the womb, statistics are quoted, in accordance with which, out of seventy-six cases remaining under observation after recovery, seventy-two were still well, without recurrence of the disease, from one to five years after the operation. Removal by the vagina is given the preference. There is a very fair discussion of the comparative merits of the clamp and ligature methods. The author prefers to tie out the uterus by catgut sutures. The technique of the operation is one which combines the best points of Martin's and Olhausen's methods. The cervix is curetted, charred, and sewed over; it is then dragged down and Douglas's pouch is opened. The peritoneal and vaginal edges are united by a running catgut suture; the peritoneal cavity is protected by a sponge fastened by a thread; the cervix is dragged backward and downward, is incised across its anterior surface and stripped from the bladder. The uterovesical peritoneal fold is then opened and the perineal and vaginal surfaces sewed together. Then the broad ligaments are tied off by means of catgut sutures passed with aneurism needles with right and left curves, the womb being cut free as each portion of the ligature is tied. As the womb is freed it descends lower and lower until all its attachments are severed. Whenever possible, the ovaries and tubes should be ligated and removed. The stumps of the broad ligament are then secured in the vaginal incision, the wound is nearly closed, a small strip of gauze is pushed up into the pelvic cavity through the small opening left, and the vagina is packed with iodoform gauze.

The subject of uterine neoplasms, illustrated by some admirable plates, is treated in a peculiarly lucid style.

Pelvic inflammation is treated at length. It is pleasant to see that there are still gynæcologists who do not scorn palliative treatment. This is given in full detail, together with a fair statement as to the proportion of permanent cures which may result from such treatment.

Ectopic gestation, though briefly discussed, is remarkable for the clearness and comprehensiveness of its teachings. In diseases of the

urethra, bladder, and ureters the method of demonstrating tubercle-bacilli in the urine is described, and attention is called to the value of iodoform glycerin injections. The section on bladder-diseases deals only with the general outline of the subject and particularly with the practical management of cases. Under diseases of the ureters is included Kelly's ingenious and now widely known method of catheterization. The book closes with a section on after-treatment of gynecological operations. This includes subheadings of rest, vomiting, drink, food, purgatives, management of the bladder, bathing, hemorrhage, flatulence, care of the drainage-tube, shock, sepsis, and after-complications, such as fistula and hernia.

The work is thoroughly practical and fully merits the more than ordinary favor with which it has already been received.

**HOLDEN'S MANUAL OF THE DISSECTION OF THE HUMAN BODY.** Edited by J. M. Langton. Sixth edition. Revised by A. Hewson, M.D. Three hundred and eleven illustrations.

Philadelphia: P. Blakiston, Son & Co., 1894.

The scholarly works of Macalister and of Morris, both of which have appeared comparatively recently, and the universal favor with which Gray is received, at least by American students, would seem to leave no place for any text-book of anatomy, even though it is arranged as a manual of the dissection of the human body. Yet the fact that this work has reached a sixth edition, the first having been published in 1851, is a sufficient guarantee as to the fact that it has filled a place in the past, and the admirable illustrations and the simple, graphic descriptions give promise that, in spite of increased competition, it will be received even more favorably than before. Over Macalister's work it possesses the very great advantage of simplicity both in nomenclature and expression. The illustrations of Gray are, on the whole, better, though many new and admirable cuts are found in Holden's work. Its particular merit lies in the fact that it fills more thoroughly than any other published work the requirements of the dissector. The text is richly annotated. Anomalies are given their due importance and the surgical bearing of anatomical teachings is not slighted. The nomenclature is simple, and the illustrations, although in many cases somewhat diagrammatic, serve their purpose in making clear the text. As a dissecting manual this work is worthy of hearty commendation, and is more calculated to win its place as a text-book for American students than the great majority of the books written by English authors.

**VENEREAL MEMORANDA: A MANUAL FOR THE STUDENT AND PRACTITIONER.** By P. A. Morrow, A.M., M.D.

New York: William Wood & Co., 1894.

The fact that Morrow has prepared this little work is sufficient guarantee of its excellence and accuracy. It consists of a series of dogmatic assertions covering the ground of venereal diseases. Some of these are open to objection. Thus, the law that syphilis occurs but once in the same individual has its exceptions. The definition of gonorrhœa ignores the specific nature of this affection. Again, nearly every venereal specialist now believes that gonorrhœal inflammation is rarely confined to the anterior urethra, but involves the whole of this canal. In the great majority of cases of chordee there is probably no effusion of plastic lymph in the meshes of the spongy tissue, but the painful erection is due to infiltration of the mucous and submucous layers of the urethra. Coincident with the development of epididymitis, cessation of the urethral discharge is an exception rather than the rule, and the swelling incident to this affection is not due to increased size of the testicle, but to enlargement of the epididymis, hydrocele, and infiltration of the loose connective tissue of the scrotum. Gonorrhœal rheumatism is often polyarticular. Such errors in statement of facts are minor defects almost inseparable from the terse, dogmatic style of the book. To compensate for this it has many major virtues. The diction is clear and direct, the teaching is thoroughly modern and evidently based on large personal experience, and the essential points have been culled with great skill.

**HERNIA: ITS PALLIATIVE AND RADICAL TREATMENT IN ADULTS, CHILDREN, AND INFANTS.** By Thomas H. Manley, A.M., M.D.

Philadelphia: The Medical Press Company, Limited.

This book seems to have been written not with the idea of popularizing any individual method for the cure of hernia, but rather for the purpose of presenting to the profession a dispassionate consideration of all of the recognized procedures employed in the treatment of this affection, allowing each one to draw his own conclusions from the facts thus presented. In regard to congenital hernia, the statement is made that a large proportion of herniæ of infants will disappear by hygienic measures alone before the end of the first year. For them no sort of mechanical apparatus should for a moment be thought of. Attention is called to the fact that in these hernias of children persisting to the walking age and treated by a truss, cure is accomplished generally. The

author holds that even though the hernias are liable to relapse between the twentieth and thirtieth years, advice should not be given to wear a truss as a prophylactic. Rather such patients should be fitted with a broad, comfortably fitting canvas or leather belt. He states that comparatively few children require operation. Among these few must be included infantile hernia proper, in which adhesions with the testis or spermatic cord render reduction impossible; incoercible, painful, incarcerated hernia; female herniæ which contain within their sacs any of the generative organs; impending or actual strangulation.

In treating hernias of the adult, after an historical review of the subject and directions for the employment of a truss and other supports, the radical cure of irreducible hernia by operation is considered. There is an interesting historical *résumé* of this subject, and a full description of the methods of Reissel, Championnière, McBurney, McEwen, and Bassini, and it is to be noted that Manley, although he has seen the Bassini operation performed repeatedly, is distinctly opposed to it. In reference to Bassini's reported two hundred and fifty-one operations, Manley says one hundred and ninety-eight passed from under observation within six months of operation.

The work closes with chapters upon the operative technique of strangulated hernia and its complications, manual and instrumental, and operative technique for incarcerated, non-strangulated, reducible hernia when treated by open incision. Finally, there is a tabulation of fifty-eight cases, beginning in 1885. The author states in his recapitulation that at the present time when he herniotomizes he purposes not so much securing a radical cure as placing the hernia in such a position that it will give no inconvenience, and that it may be safely controlled by a truss support. He follows no orthodox plans in operations, but is guided by the indications of each individual case.

**DISEASES OF THE SKIN: AN OUTLINE OF THE PRINCIPLES AND PRACTICE OF DERMATOLOGY.** By Malcolm Morris. With eight chromo-lithographs and seventeen wood-cuts.

London, Paris, Melbourne: Cassell & Co., Limited, 1894.

This admirable manual, written, as it evidently is, by a keen, clever specialist of exceptionally wide experience, most satisfactorily meets the requirements of the American practitioner of medicine, in that it gives him a clear, comprehensive picture of every skin-affection for the cure of which there is any chance of his

being called, and formulates for him a system of therapeutics in the following of which he can feel well assured of obtaining the best results.

Perhaps the most striking feature of Morris's work is the clearness of his style and his power of summarizing in comparatively few words facts which in other books are often spread over as many pages.

At the first glance the book would seem to have been written off-hand, but on more careful study it shows not only the results of wide clinical experience, but a knowledge of contemporary literature and a richness of reference often missed in more pretentious volumes.

A praiseworthy effort in the direction of simplicity is made in the classification of skin-diseases. This is based on modern pathological research, and in the main follows the lines traced by Unna. No violence is done either to the intelligent reader or to diseases the etiology of which is yet obscure, since these are very sensibly left unclassified.

The text is elucidated by many colored plates, such as we are accustomed to expect in atlases, but which form a pleasant surprise in a work as unpretentious as this.

This manual is a valuable addition to the bibliography of skin-diseases, and should receive a hearty welcome at the hands of the American practitioner.

**LECTURES ON AUTO-INTOXICATION IN DISEASE, OR SELF-POISONING OF THE INDIVIDUAL.** By Ch. Bouchard. Translated, with a Preface, by Thomas Oliver, M.A., M.D., F.R.C.P.

Philadelphia: The F. A. Davis Company, 1894.

Much of the literature regarding the subject of auto-intoxication in disease is so much behind the time and describes so little of the original investigations into this subject which have been made within the last few years that we were seriously in need of some such work as that now under review. This volume of three hundred pages has been written by a French author of wide reputation and thorough reliability, and in its thirty-odd chapters takes up in an interesting way pathogenic processes in general, the production and elimination of poisons, the toxicity of urine, intestinal antiseptics in health and in disease, the toxæmia of diabetes, and finally the general therapeutics of auto-intoxication. Finally, we would call attention to the fact that Gamaleia's book on "Bacterial Poisons" and Trouessart's book on "Antiseptic Therapeutics" are published by George S. Davis, of Detroit, at twenty-five cents a volume, while this work is published by the The F. A. Davis Company, of Philadel-

phia. We call particular attention to this, as some confusion seems to exist in the minds of our readers as to the books which are published by these two publishing houses.

**ANTISEPTIC THERAPEUTICS.** By E. L. Trouessart, of Paris, France. Translated by E. P. Hurd, M.D. Vols. I. and II.

Detroit: George S. Davis, 1894.

This interesting work upon antiseptic therapeutics forms a valuable addition to the literature of therapeutics in its relation to the development of toxins and the micro-organisms which produce some of them, and forms a valuable supplement to the small volume in the same series on bacterial poisons by Gamaleia. To the average physician, who cares more for the results which he can obtain than for the etiology of the affections which he treats, the second volume of this work will prove the more interesting and valuable. It is copiously dotted with prescriptions original with the author or quoted from other authorities, and it may be considered as a practical application of the information gained from a study of the subject in Vol. I. It is of very great interest to learn that so much can be done in the treatment of disease on a purely rational basis, and these little volumes provide a careful summary of the best views of the best men at this time concerning the influence of auto-intoxication on man. As the volumes cost but twenty-five cents in paper covers, and are well printed and bound, they should find a wide sale and much appreciation among the profession.

**A TEXT-BOOK OF THE THEORY AND PRACTICE OF MEDICINE.** By American teachers. Edited by William Pepper, M.D., LL.D. Vol. II. Illustrated. Philadelphia: W. B. Saunders, 1894.

Nearly eight months ago the first volume of this valuable book made its appearance, and those who were wise enough to subscribe for it at that time have waited anxiously for the appearance of Vol. II., which it was thought promised more than Vol. I. We think that these expectations have been thoroughly realized, and that Vol. II. very distinctly surpasses its predecessor in value. A carefully written scientific article upon the biology of bacteria and infection and immunity opens the volume, by the pen of Dr. William H. Welch, of Johns Hopkins University. A very large part of it—some three hundred and twenty-five pages—are contributed by Dr. William Pepper. As with all works which are written by various authors, marked unevenness in the value of each necessarily occurs. Perhaps the most unsatisfactory from a therapeutic point of view is the article

of Dr. Delafield, of New York, upon lobar pneumonia. It is not extraordinary that the mortality of this disease is as high as it is if the treatment here recommended is carried out so irrationally. No distinction is made as to the treatment of the disease in its various stages, and we are simply told that this drug or that drug may be employed, without much preference being expressed for any plan or distinct indications being named for the use of each drug. We notice that digitalin is recommended in place of the other preparations of digitalis, although it is universally recognized that the action obtained from this substance is not identical with that of the tincture. We think it unfortunate that so little reference is made to the treatment of pneumonia by the injection of toxins. This subject should not have been referred to at all, or else sufficiently considered to give some information on the subject. Under the articles on kidney-disease we notice that the term of acute "productive" nephritis is introduced instead of acute diffuse nephritis, and it is natural that in these articles the well-known views of Dr. Delafield concerning the distribution of inflammatory processes in the kidneys are thoroughly exploited.

In the article by Dr. Fitz upon acute peritonitis we note with much interest the position which this eminent authority maintains in regard to the use of salines. He supports the views already expressed in the editorial columns of the THERAPEUTIC GAZETTE and also those of Dr. Maurice Richardson,—namely, that the saline treatment of peritonitis is not to be resorted to unless the cause of the disease in an individual case is thoroughly understood and the physician is confident that active ulceration or perforation of the bowel is not the cause of the trouble. Opium is the remedy which Dr. Fitz recommends, thus supporting the views originally expressed by Alonzo Clark. The index completing the volume is very full and complete.

The work is a credit to American medicine, to its gifted editor, and to the gentlemen who have done so much to make its pages valuable.

**NOTES ON NURSING IN EYE-DISEASES.** By C. S. Jeaffreson, M.D., F.R.C.S.E.

Bristol: John Wright & Co., 1894.

In the last number of the THERAPEUTIC GAZETTE we had occasion to refer in complimentary terms to a book on an allied topic, as being the first one of its kind which has come to our notice. Usually a new departure in any direction is speedily followed by others in the same line. Evidently this is true so far as

manuals on ophthalmic nursing are concerned. Dr. Jeaffreson's small treatise of less than one hundred pages emphasizes general rules of nursing applicable to ophthalmic practice, and chiefly those which he has found useful in his own public and private work. In his preface he states that it has been suggested to him that a short anatomical and physiological description of the organs of vision should have been included, but we think he is right in having omitted it, and have always believed that both in the lectures to nurses, as well as in the books that have been written on the subject, too much attention has been paid to these anatomical and physiological considerations and too little to the practical side of the subject. The present book is satisfactory in the main, and gives to those who are interested in the subject of nursing in eye-diseases the most important directions for the carrying out of the various duties which will fall to their hands, and so far as we can see, in the space devoted to the topic, all of the necessary directions are plainly and clearly enunciated. It is promised that if the book reaches a second edition, which we have no doubt will be the case, both the matter and the illustrations shall be extended.

STUDENT'S MEDICAL DICTIONARY. By Alexander Duane, M.D.

Philadelphia: Lea Brothers & Co., 1893.

One might perhaps be pardoned a little surprise at the appearance of still another medical dictionary, but the work before us is one that will well bear comparison with its fellows. The book consists of a series of major titles, printed in heavy type, each beginning a separate paragraph, a series of subordinate headings being placed in the body of the paragraphs. The derivation of each word is given in brackets, the root words being placed in italics. The Greek letters are given in those of our own alphabet, which seems rather a questionable procedure, as the advantage given to those unacquainted with Greek can hardly, in the opinion of the reviewer, compensate for the loss of the Greek letters.

Space has been often saved by the omission of obsolete words, much of which has been well utilized under the important headings by the insertion of matter descriptive and explanatory, when a mere definition would hardly be sufficient. The author has arranged in tabular form the muscles, arteries, nerves, and canals, making easy and valuable tables of reference. Under the more important diseases a short sketch is given of their causation, symptoms, and treatment, and a brief description is found

of the structure and functions of the main organs. Under each drug a short outline is given of its physiological actions and therapeutic uses, also all its preparations official in the latest editions of the Pharmacopœias of the United States, Great Britain, and Germany. The definition of each word is clear and full, and Dr. Duane's book fully deserves to be ranked among the first works of its kind.

### LONDON.

(From our Special Correspondent.)

From time to time considerable interest has been evoked in the medical world by statements to the effect that patients suffering from malignant disease have been considerably benefited by an intercurrent attack of erysipelas. The evidence on which such statements are based is indisputable, and it was at one time suggested that a legitimate treatment for inoperable malignant tumors would be to put the patients in the way of becoming infected with erysipelas. This was actually done in several cases; but the objections to such a proceeding were numerous, the chief of them being the uncertainty whether the patient would contract the disease at all, and the doubt whether the erysipelas, if successfully communicated, might not prove at least as dangerous as the original malignant disease. In one or two cases, in fact, it was found impossible to control the erysipelas, the patient succumbing rapidly to its influence. Such cases naturally disinclined medical men to run any further risks of a similar nature, and it was not until the bacteriology of erysipelas became better known that we heard of further experiments. When it became possible to isolate a streptococcus from a case of erysipelas, to cultivate it under artificial conditions, and so to modify its pathogenic properties as to have the effects of its introduction into the economy fairly under control, inoculation with such a culture in a case of malignant disease became at once a more rational proceeding. Many cases have been treated in this way, notably by Spronch, of Utrecht, and Coley, of America, and the results have been extremely encouraging. Still, however, it has been felt that it is a somewhat dangerous expedient to adopt, for it is never possible to absolutely assure one's self that a culture of the streptococcus, thus employed, may not unac-

countably take on extremely virulent characters and produce unpleasant results. It has also come gradually to be admitted that any good results produced by the infection have been due to toxins resulting from the growth of the microbes in the tissues, the natural outcome of such an idea being to try and secure the formation of the same substances outside the body, to free them from micro-organisms, and to employ them in the same manner as one would any other drug. I believe that Coley has actually done this, and has employed filtered cultures of the *S. erysipelatis* with some measure of success, especially in cases of sarcoma. A still further refinement, however, seems necessary. It is hardly satisfactory to work with filtered cultures, as one can never be sure of the amount of active substance contained in them. What one actually wants is to have the active substance isolated from the culture and kept in a dry state, so that it may be administered in weighed quantities, and may also be free from the liability to undergo change, inseparable from all solutions of such substances. Roger, in Paris, and Bokenham, in this country, have both succeeded in isolating a toxin from cultures of the *S. erysipelatis*, which belongs to the class of albumoses, and which seems to possess all the properties of filtered cultures. I do not know whether Roger has done so, but Bokenham has succeeded in preparing the above-mentioned albumose, and preserving it in a dry state over sulphuric acid, so that it retains all its activity for at least several weeks. It was capable of use in weighed doses, and gave rise to febrile reaction in animals. Quite recently, Mr. Bokenham has tested the effect of this substance in a case of inoperable sarcoma of the back, and already the results are most promising. A weighed dose was dissolved in sterile distilled water and injected under the patient's skin, not necessarily into the affected part. No effect was observed, either local or general, for some hours; then there began a gradual elevation of temperature, until at length the thermometer stood at a point about three degrees above normal. At the same time the nodules of tumor became tender and more prominent, showing distinct signs of congestion. Next day some of the nodules showed evident signs of breaking down, a wound over one of them opening and emitting a yellowish discharge. On the next day the temperature was still somewhat elevated and the wound discharging, some small lumps of tumor tissue becoming detached. The other nodules were distinctly softer to the touch and seemed to be undergoing a process of dispersion. A second

injection was followed by very similar results, and the outlook was altogether encouraging, when an unfortunate accident put an end to the supply of toxin.

It is hoped, however, to continue the treatment at no distant date, the chief difficulty being to obtain a streptococcus of such great virulence as to yield a toxin of the necessary activity to produce a rise of temperature, without which apparently no effect is produced, either local or general. I shall take an early opportunity of referring again to this most interesting case.

I saw an interesting case a fortnight or so ago at the Queen's Jubilee Hospital,—a small general hospital in West Kensington. The patient, a middle-aged woman, had for years been suffering from obstinate lupus, there being a patch of particular severity situated just over the right wrist and extending nearly round the forearm. All manner of treatment—by scraping or by local applications—had been tried without avail. It was decided, as a last effort, to very thoroughly scrape the whole of the affected surface and to apply large skin-grafts to the parts. This was done, all the diseased tissues being as far as possible removed and the tissues laid bare almost down to the muscular layer. With a sharp razor very thin sheets of cuticle were shaved from the patient's own thighs, in such a way that pieces nearly two inches square were got of about the thickness of blotting-paper, without causing more than a slight superficial oozing from the denuded parts of the thigh. Several of these were sliced off, each being immersed in some warm water until sufficient had been obtained to cover the whole of the scraped surface. The grafts were then applied and covered with a sheet of oiled silk, the outer surface of which was then dusted with iodoform and covered with aseptic dressings. After a few days it was found that nearly all of the skin thus grafted had become attached, the place presenting a healthy granulating surface. Every day the oiled silk was removed with as little disturbance of the subjacent parts as possible, washed in carbolic lotion, and replaced. Iodoform was again dusted on and the whole covered. At the present time, more than a month since the operation, the patch still shows no signs of breaking down. It is covered with healthy skin, and the patient professes complete freedom from pain, a condition she has not experienced in some years. I hope to have an early opportunity of trying this operation in another similar case. I am told that it has already been practised in several instances in Australia and New Zealand.

### QUININE AS A REMEDY FOR ENURESIS.

By CHARLES S. POTTS, M.D.,

Instructor in Nervous Diseases in the University of Pennsylvania;  
Assistant Neurologist to the University Hospital.

IN a communication to the Philadelphia Neurological Society, which was published in the *Journal of Nervous and Mental Diseases* for April, 1893, Professor H. C. Wood proposed the theory (for the proof of which we refer the reader to the original paper) that choreic movements were due to two factors,—viz., first,

that the motor power of the spinal cells is weakened; and, second, that the power of the inhibition apparatus—the so-called Setschenow's centre, which controls motor discharge from these cells—is weakened to a greater extent than is the discharge power. As quinine is a stimulant to the inhibitory centre, its use was proposed as a remedy for chorea.

At the meeting of the American Medical Association, held in June, 1893, the writer, in conjunction with Dr. W. A. N. Dorland, presented a paper, subsequently published in the *University Medical Magazine* for July, 1893, and also in the *Journal of the American Medical Association*, in which they detailed seven-

teen cases of chorea treated with this drug with flattering success.\*

Among the cases so treated was one, the history of which will be detailed below, in which enuresis was a marked and troublesome symptom, and it was noted that as soon as the quinine was administered this symptom disappeared. At that time it occurred to the writer that this fact was a confirmation of Dr. Wood's theory, as enuresis is probably caused in a large number of cases by the failure of the higher centres to properly control the reflex act by which we empty our bladders, associated with a general lack of muscular power and tone, and enuresis is a more or less frequent accompaniment of chorea. It therefore seemed rational that quinine should prove useful in this condition, provided all other possible causes, such as adherent prepuce, rectal irritation by worms, etc., were excluded.

While the number of cases in which it has been tried is exceedingly small (only two), it has seemed to be worth while to report them, for the reasons that they seem to be a confirmation of Dr. Wood's theory for the choreic movement, and that others may be tempted to try the drug in similar cases. It should be borne in mind that the remedy must be administered in full doses.

CASE I.—T. A., aged fifteen, a school-girl, presented herself at the clinic on June 1 with her fourth attack of chorea, and with the additional history that she had always, since infancy, wet the bed at nights. No other cause for this than her general neurotic condition being present, she was given 6 grains of quinine sulphate five times daily. Five days later she reported with the choreic movements lessened, and she also stated that she had not wet the bed since taking the medicine. This improvement continued, the quinine being in the mean time increased to 40 grains daily, until June 26, when Fowler's solution was substituted. On the 30th she returned, saying that she had again wet the bed. She continued to do this until July 3, when the quinine treatment was returned to, with the result that the enuresis immediately ceased.

This treatment was continued, together with syr. hypophosphit. co., for several weeks, after which the dose of quinine was gradually reduced, and when last seen the patient was perfectly well.

I would call special attention to the facts of the enuresis returning as soon as the use of the quinine was stopped, and to its immediately

ceasing when the use of the drug was returned to.

CASE II.—M. McL., aged ten, a school-girl of nervous temperament and small for her age, came to the clinic on July 17, with the history that, since having scarlatina when five years old, she had wet the bed *once and sometimes twice nightly*. No apparent cause being present for this, she was ordered 2 grains of quinine four times daily. On July 21 she reported as being much better, and had missed her nightly attack the second night after beginning the medicine. This being the first time she had missed since the beginning of her trouble, the medicine was increased to 5 grains five times a day. Five days after this she returned, stating that she had not wet the bed since her last visit. The dose was then decreased to 2 grains t. i. d. On the 31st she reported having had one attack. From this date until August 11 she had two attacks, and her medicine was increased to 16 grains daily, with the result that she had only three attacks from the 11th until the 28th. The quinine was then stopped, and she was given a tonic and small doses of belladonna. She was not seen from this date until December 4, when she stated that she had not had an attack since her last visit in August.

In this case, as in most of our cases of chorea, the quinine seemed to lose its effect in time, so that it was necessary to continually increase the dose; it was for this reason that its use was stopped and the other treatment substituted. It would seem that in this condition, as in chorea, quinine may prove useful to produce a rapid effect, but to secure permanent results the system must be built up by tonics and other appropriate measures in order to increase the general muscular tone, which it will be remembered is also lacking. If subsequent trials should give similar good results, the use of quinine should be preferable to that of belladonna, the old stand-by in this class of cases. In our paper upon the use of quinine in the treatment of chorea, we called attention to the fact that the patients bore large doses without experiencing any signs of cinchonism; we might almost compare it to the tolerance of typhoid fever patients to large amounts of alcohol. Full doses of belladonna always cause uncomfortable and annoying symptoms; therefore we escape these; and even if the symptoms of cinchonism should manifest themselves, they are much more easily borne. In using quinine, also, we are substituting a comparatively harmless drug for an active poison, and hence do away with the dangers of possible overdoses being administered and consequent

\* This success still continues.

poisoning, which is a desideratum, especially in dispensary patients. Again, in the limited experience which we have had, it has seemed that the quinine has acted quicker than the other commonly employed remedies.

UTERUS.*

CLINICAL LECTURE DELIVERED AT THE JEFFERSON HOSPITAL,  
OCTOBER 24, 1893.

BY E. E. MONTGOMERY, M.D.,  
Professor of Clinical Gynecology, Jefferson Medical College;  
Gynecologist to Jefferson and St. Joseph's Hospitals;  
Obstetrician to Philadelphia Hospital.

SACRAL RESECTION.

**G**ENTLEMEN:—Two weeks ago I brought before you this patient, with the following history: She is twenty-three years of age, unmarried, and has been suffering for several months with disease of the rectum. She entered the hospital in August last, and upon examination the entire rectum was found to be ulcerated upon an indurated base. She was suffering intense pain from passage of feces over this ulcerated surface, and quite a stricture had formed. At that time, as a preliminary operation, Dr. Hearn did what is known as the Madyl operation for colostomy. This consists in making an incision in the inguinal region into the peritoneal cavity, raising up the colon, and passing beneath it a glass rod, packing around the opening iodoform gauze to produce inflammatory adhesions fixing the gut in the wound. After the union became sufficient, the intestine was opened by a thermo-cautery, and later the intestine cut through. As a result of this operation, all the evacuations have taken place through this opening, the bowel has been relieved from the irritation, and the patient has been very much more comfortable. Upon examination it was found that the rectum was involved about four inches up. Infiltration had extended through the vagina, so that the posterior vaginal wall was firm and rigid; there was a point of induration and ulceration over the perineum which extended along the posterior margin of the vulva half-way up the labium upon either side. It was quite evident that any operation to afford hope of radical cure would necessitate the removal of a good portion of the rectum, the posterior wall of the vagina, the perineum, and probably the uterus.

Accordingly, two weeks ago I brought her before you, made an incision over the sacrum, extending from the left iliac synchondrosis across the median line, terminating at the side of the anus. Flaps were dissected back, laying bare the coccyx and lower end of the sacrum. The coccyx was enucleated; a part of the right side of the lower two sections of the sacrum removed with bone pliers. Bleeding was arrested by sponge pressure and hæmostats, and the rectum pushed off from the anterior surface of the sacrum. \*The rectum was then dissected on either side, seizing vessels with hæmostats as they bled, and with the finger in the vagina the perineum was seized and cut away until beyond the border of the involvement of the labium. On either side the vagina was cut through until the fundus was reached. We then opened the peritoneum to the right side, grasped the fundus of the uterus, and ligated its broad ligaments, securing in this way the ovarian and uterine arteries, and cut away the uterus on the right side. The left side was then ligated in the same manner and the uterus and ovaries removed. The rectum was now drawn down until healthy tissue was reached, which was then cut across, and as it was found that the rectum was filled with old indurated fecal masses, the wound was covered with gauze pads, the rectum held down, and with the finger these masses were removed. After the rectum was cleansed, the peritoneal opening was sewed up, the bowel stitched fast to the mucous membrane of the anterior wall of the bladder, and laterally and posteriorly to the skin. The edges of the skin on either side were drawn down and fastened to the vagina by a continuous catgut suture. This was done hurriedly, owing to the extreme debility of the patient, she being exceedingly anæmic, pulse imperceptible at the wrist, and the respiration bad. Hypodermic injections of strychnine were given while the operation proceeded, until about one-third of a grain had been administered. It was given subsequently every half-hour, and later every hour, in  $\frac{1}{20}$ -grain doses, until the patient recovered from the shock. Shock was necessarily profound. The next morning after the operation her temperature ran up to 102° F., which was evidently reaction from the shock, as it soon subsided. About a week after the operation she had a severe chill; temperature rose to 105° F. On examination it was found that some secretions were locked up in close proximity to the peritoneal cavity, and it was undoubtedly these which gave rise to the elevation of temperature, for, as soon as they were opened and

drained, the temperature subsided. Some sinuses were opened up, the cavity thoroughly washed out with sulphurous acid solution, the parts dressed twice daily, when the temperature subsided and is now normal. She eats and sleeps well. There is a larger surface here to cicatrize. It will take some time before the cicatrization is complete. You notice on the left side the walls are more firmly held down and the line of the raw surface is much narrower than upon the right. This is due to the fact that, in separating the buttocks, traction has been made from the right side, causing the sutures to be pulled out. The wound is perfectly clean and healthy; the rectum is united to the skin externally and to the vagina.

This operation of resection was first done by Kraske in 1885, and it was performed and advocated by him in cases of rectal disease involving the middle and higher part of the rectum. The procedure has lately been suggested by Hochenegg and Herzfeld for removal of the uterus and ovaries in diseased conditions. A number of modifications of the Kraske operation have been suggested in the incision of the sacrum, some of them with a view of restoring the parts to the normal condition after the operation is completed. Thus, in making the sacral incision, we made it obliquely, leaving one side of the sacrum undisturbed. Bardenhauer modified this by making transverse section below the third sacral foramen. I think the preferable procedure, however, is to remove but one side, as thus the nerves making their exit from the fourth sacral foramen are undisturbed. These nerves supply the rectum and bladder, and if we destroy them upon both sides it will necessarily cause a certain amount of irritation of those viscera. If one side is left undisturbed it compensates for the loss of the other, and the patient suffers no inconvenience. We dwell upon the importance of making the incision below the third sacral foramen, for the reason that, if this foramen is involved, it would result in injury of the third sacral nerve, which assists in the formation of the sacral plexus, and injury of it would consequently influence locomotion in the lower extremities. When this operation was proposed some time ago, a number of physicians objected to it, claiming that it would be likely to result in injury to the spinal cord; they had forgotten, however, that the cord was not continued below the second lumbar vertebra, excepting as the filum terminale, and in the lower part of the sacrum there is no canal. Consequently there is no danger of injury of the spinal cord in our procedure. The side of the vertebra removed will

depend somewhat upon the purpose of the operation. If the operation is on the rectum alone, you would make the incision on the left side, as the bowel is situated more to that side. If you wish to operate on the uterus without disturbing the rectum, the sacrum should be resected on the right side, when there will necessarily be less displacement of the rectum. With the removal of the sacrum there is not infrequently considerable bleeding from the median sacral artery. This is, however, readily controlled by sponges or may be seized by the hæmostatic forceps. The vessels on the side of the rectum are usually controlled by hæmostats. When the vessels are torn, hemorrhage is usually slight.

In reviewing the operation on this patient it occurs to me that I made a mistake in one part of it, and that was in having cut away the diseased bowel before I had closed the peritoneal opening. The opening in the peritoneum might have been readily sewed up before the bowel was opened, thus decreasing the danger of fæcal infection. Suturing the intestine to the anterior wall of the vagina, and posteriorly to the skin over the sacrum, made the artificial anus in the upper part of the cleft. Now, if this patient recovers her health completely, we may very readily open around the site of the former operation, pick up the two ends of the bowel, and establish an anastomosis, thus reforming a continuous canal. This, however, will be left entirely to the option of the patient. The experience of this case has, however, demonstrated the advisability of preliminary colostomy in order to prevent the passage over the newly-united surfaces of a large mass of fæces. If the wound closes completely there will be left simply a cleft at this point into which the fæcal matter will pass, the anterior margin of which is formed by the anterior wall of the vagina. This is, of course, an exceedingly unpleasant condition, but we have to consider the fact that this individual was suffering from a diseased state which was beyond all relief otherwise than by such a procedure. The operation of sacral resection I have done in five patients. In the first we removed the uterus, ovaries, and about three inches of the middle part of the rectum. The two ends of the bowel were stitched together, leaving a sphincter below. The patient had not had an effective movement of her bowels for several weeks, so there was a large accumulation of hard fæcal matter in the upper part of the intestine. A couple of days later the fæcal matter was forced against the wound, causing the lower segment of the bowel to be pushed off and the extravasation of

fæces into the wound. This necessitated re-opening the wound, scraping, washing, and curetting away the fæcal matter, and the patient was kept perfectly quiet thereafter. Four weeks later the ends of the gut were dissected up and brought together by sutures, which resulted in union. The patient succumbed six months subsequently to a return of the disease.

The second patient was one with cancer of the cervix; a woman who had never given birth to children, and in whom, consequently, the vagina was undilated. The uterus was fixed by pelvic exudation and involvement of the ovaries and tubes. In that case the incision was made to the right side of the bone, the rectum pushed to the left, the peritoneum opened, the uterus seized, lifted up, and ovaries, tubes, and uterus removed. After ligation of the vessels, the vaginal walls and the peritoneum above it were brought together by sutures, shutting off the vagina from the abdominal cavity. The peritoneum posteriorly was then closed and the wound closed with sutures, leaving a gauze drain. After a somewhat slow convalescence, the patient entirely recovered and enjoyed good health until a year after the operation, when she returned to me, showing the presence of epithelioma of the upper part of the vagina. She was then subjected to curetting and cutting away of the diseased tissue as far as could be done and the cavity packed with iodoform gauze. She recovered, the surface healed over completely, and although something over a year has passed, she has not as yet had any return.

The third operation was performed for stricture of the rectum, extending about four inches up the gut. Five inches of the bowel was removed and an artificial anus made at the junction of the lower part of the sacrum. This was done two years ago this coming November. Three months ago there was developed a cicatricial ring around the external opening. This contracted until it would not admit the point of the little finger. A month ago section was done, and the patient has now been at home two weeks. I saw her last night in Altoona, and the bowel was perfectly healthy.

The fourth patient was a woman over fifty years of age, upon whom we operated in this hospital a year ago. She was suffering from cancer of the rectum, which had infiltrated the posterior wall of the vagina. The portion of the bowel and of the posterior wall of the vagina were removed and an artificial anus established posteriorly. This patient had suffered for over a month from loss of rest, continued pain and distress from futile efforts to evacuate the bowels, and consequently was not in a good condition

for operation. Suppression of urine followed, and she died at the end of forty-eight hours.

The fifth case is the one I have now before you; so in these five cases I have given you my experience in this work, in which four patients have survived and one died. In this, as in all my work, I propose to show you not only my successes, but to tell you of my failures. I do not believe, as a teacher, I am doing rightly if I do otherwise.

#### OPERATION FOR FÆCAL FISTULA.

In harmony with this purpose, I bring before you a patient upon whom I operated last March, in this house, for a large collection of pus in the pelvis. It was necessary in removing this pus collection to tear up extensive adhesions, after which a gauze drain was introduced. A few days after the operation, when the gauze had been removed, there was noticed coming from the fistulous tract left by the gauze drain fæcal matter, which increased in quantity until at one time the greater part of the movements came through the abdominal wound, and from the appearance of the material thrown out it was evident that the opening was situated in the small intestine. The patient was consequently rather poorly nourished. I operated on this patient three weeks ago last Friday, with a view of finding out the point at which the fistula opened, and closing it. I assure you there is no operation that is more trying, requires more patience and courage, than one done for a fistulous opening which is situated deeply in the abdomen and discharges from which have given rise to extensive inflammation and adhesions of the intestines. Everything was found matted together. After tearing up the adhesions, two openings were seen in the intestine, into one of which the end of a pencil could be introduced, while the other would admit the finger. These openings were closed with continuous catgut suture. In opening the wound we had to go through an abdominal surface that was infiltrated from contact of fæcal matter. It was in a state, consequently, of inflammation and induration. The whole external surface of the wound was scalded with fæcal matter and, as a result, was with difficulty cleansed. The recti muscles were so rigid that in breaking up the adhesions and exploring the cavity thoroughly it was necessary to make a transverse incision. In closing the wound, buried silkworm-gut sutures were used, and considerable traction was necessarily made in order to bring the surfaces in apposition. The wound in the intestines has been completely relieved. The bowels move regularly, and the patient's general con-

dition is better. There has been some inflammation, however, in the line of the wound, and an abscess has formed. I have taken out one of the deep sutures in the upper part of the wound, and I notice to-day inflammation in the lower portion. It will probably be necessary to remove the other sutures before she is entirely relieved of this distress.

#### ANÆMIA.

The next patient is a young lady, whom I brought before you some time ago suffering from profound anæmia, with painful menstruation, or rather pain preceding menstruation for a week, which was felt in the right side and continued during the entire period. She was placed upon a plan of treatment which consisted in regulation of the bowels, administration of quinine, strychnine, and arsenate of iron, good nourishing food, and moderate outdoor exercise. As a result she is greatly improved, she has menstruated without pain, and the pain and distress in the pelvis have disappeared. You notice by her appearance that she is very much improved, showing more blood in her face. I bring her before you to emphasize the assertion that conservative measures should be practised in these cases of supposed inflammation of the ovaries, and that on no account should pain be considered as an indication for an abdominal operation. Let an abdominal operation be the very last thing done, and only after trying all other means. I can assure you there is no class of cases which give promise of less favorable results from the removal of the appendages than these very patients in whom there is an absence of enlargement or marked change and where the operation is done for pain alone. There are cases, probably, in which there is a certain amount of neuritis to which the pain is due, and the removal of the appendages does not necessarily affect it. Such patients are often neurasthenic, and we may operate and reoperate and they will continue to suffer just as much pain.

#### RETROFLEXION OF THE UTERUS.

The next patient is a woman forty-nine years of age, who comes to us through the kindness of Dr. Eshleman, a graduate of last year. She complains of considerable pain in the abdomen. She has had eight children, three of whom were instrumental, and after each confinement was laid up for a number of weeks, suffering from pelvic inflammation. She has had five miscarriages, convalescence after each of which was slow. On examination we find a mass situated in the posterior part of the pelvis, which is

movable, and between it and the cervix there is a distinct angle. Let me impress upon you in examining patients to proceed carefully from the time the fingers are introduced; indeed, examine by inspection before their introduction. In normal conditions the labia minora are hidden from view by the labia majora. If they vary from this condition, there is just to that degree a variation from the normal. If the vulva stands open, you will realize that there must be a loss of control of the sphincter. Inspection also would disclose if there is any protrusion from the vulva. As I turn this patient around, you notice the anterior surface projects immediately below the opening of the urethra. This projection you will recognize as a slight prolapse of the anterior wall of the vagina. As the fingers pass up, you notice the condition of the cervix, and here the anterior lip is the longer, while the posterior is flush with the vagina. We notice also that the cervix and the os look downward in the axis of the vagina. Now, as has been said, in this patient the uterus is large, and between the cervix and the mass behind there is a distinct angle recognized, although the two masses are evidently parts of the same body. The uterus is found movable, and with two fingers placed beneath the fundus, pressing upward, I am enabled to restore the uterus apparently to its normal position, although the fundus of the organ cannot be felt forward. Now, this mass, felt through the posterior cul-de-sac of the vagina, may consist of a growth of an ovary, of an exudation from the posterior surface of the uterus, or of a fibroid growth projecting from its posterior wall. That it is not an exudation is evident from the fact that the uterus is freely movable; that it can be replaced in its normal position. There is no irregularity upon it; there is an absence of that sensation of fluctuation which is not uncommon in such conditions. A fibroid tumor in this region is not an infrequent occurrence. It is readily distinguished by the conjoined manipulation, pushing the fundus forward before bringing it in contact with the external hand; in this way we are enabled to determine the fact whether a tumor is present and the measures to be resorted to for its removal. As to the possibility of retroflexion, the situation of this mass posteriorly, the angle between it and the cervix with which the connection may be traced, or inability to determine a mass, in the normal situation of the fundus, its size and shape, all lead me to be confident we have to deal with a retroflexion of the uterus. Retroflexion is not an unusual occurrence following parturition. The organ

settles downward, comes near the axis of the vagina, and as it does so the intra-abdominal pressure is directed against the uterus until it is driven down. There is no class of cases that are more difficult to treat by mechanical means than these very ones of retro-displacements; the ligaments become so relaxed that it is necessary to use an instrument sufficiently large to keep it up. This is likely to lead to still further rolling backward of the fundus and to its being pinched between the cervix and the uterus, so that in cases of marked retroflexion I prefer to resort to measures to fix the uterus forward. Now we may do one of two operations for fixing the uterus forward. One of these consists in shortening the round ligaments,—an operation known as the Alexander. The other—ventro-fixation—by opening the abdomen, drawing up the uterus, and stitching it fast to the lower angle of the wound by buried sutures. Of these two procedures I prefer the latter, for the reason that but a single wound is made, while in the Alexander operation there are two. In the Alexander operation the round ligaments are not always easily found. They are frequently atrophied, do not run out well, particularly if there has been any inflammatory disease in the pelvis, and even when drawn out they may be so attenuated as not to be serviceable. The operation is not always free from danger, as the manipulation necessary to find the ligaments sometimes leads to suppuration, and if a ligament becomes infected it may slough off, slip backward, and carry infection into the peritoneal cavity; while with ventro-fixation we are able to see the uterus, draw it well forward, and make sure that it is in its proper position, and thus establish its more secure fixation. This is the operation we will advise in the patient before us.

#### THE PHYSIOLOGICAL ACTIONS OF ALCOHOL.

ABSTRACT OF A PAPER PRESENTED TO THE SECTION ON THERAPEUTICS OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS, HELD AT WASHINGTON, D.C., SEPTEMBER 5, 6, 7, AND 8, 1893.

BY DAVID CERNA, M.D., PH.D.,  
Demonstrator of Physiology and Lecturer on the History of Medicine in the Medical Department of the University of Texas;  
formerly Demonstrator and Lecturer on Experimental Therapeutics in the University of Pennsylvania;  
Spanish-speaking Secretary (Section on Therapeutics) of the First Pan-American Medical Congress, etc.

ALMOST from time immemorial alcohol, in some form or other, has been used as a beverage the world over, and for a long time as a remedial agent in the treatment of disease. Without attempting to discuss the uses of the

drug in disease, a subject in itself quite extensive, I will confine myself to a careful study of the influence which alcohol exercises on the various parts of the economy,—that is, its physiological actions.

Both experimental and clinical observations have shown that alcohol acts decidedly on the different systems, producing changes either temporary or permanent, according to the amount of the drug ingested and the time employed in its administration. How such changes are brought about by the actions of alcohol it is the purpose of this research to examine and, if possible, to determine. The evidence which I will bring forward shall be mainly experimental.

#### GENERAL ACTION.

The effects produced by alcohol in small amounts are those of general stimulation, followed by those of depression when given beyond what may be termed the true physiological limit. In toxic doses, when administered for a short or for a long time, there are produced two conditions well known and sufficiently described by various writers on the subject,—acute and chronic alcoholism.

Alcohol-poisoning does occur, and, whether in the acute or chronic form, it often produces death *per se*. In many fatal cases death has been preceded by convulsions.\* How death is caused by the drug has not been very accurately determined. It is certainly often produced by failure of the respiration. Such an observation, at least, I have frequently made in the course of my experimentation upon the lower animals.

But the actions of alcohol are so varied that I will endeavor to study them on the different systems separately.

#### ON THE NERVOUS SYSTEM.

*On the Peripheral Nerves.*—When a very small amount of alcohol—say about 5 drops well diluted with water—is injected hypodermically into a common frog (*Rana esculenta*), there are produced phenomena of general excitability, as is evinced by restlessness of the animal, hurried respiration, slightly increased reflexes, and acceleration of the heart's action. These effects soon pass off and the batrachian resumes its normal condition. That alcohol, in minute quantities, does excite the peripheral nerves appears to be demonstrated by the results of the following experiments:

*Experiment 1.*—Took a medium-size frog. Ablated cerebrum, and, after shock had passed,

\* *Philadelphia Medical Times*, vol. vi. p. 463.

reflex action, as tested with acidulated water, was manifested in twelve seconds. Injected under the skin 5 drops of alcohol well diluted with water at 12 M. 12.15, reflex action in ten seconds; 12.20, reflex action in ten seconds; 12.30, reflex action in eight seconds; 12.50, reflex action in ten seconds.

*Experiment 2.*—Medium-size batrachian. Destroyed brain, tied the blood-vessels of right leg, and waited for the disappearance of shock. Reflex action was then tested as in previous experiment. It was manifested in both legs in ten seconds. Gave hypodermically, at 10 A.M., 5 drops of alcohol diluted with water. 10.20, reflex action in left leg in eight seconds, in right leg in ten seconds; 10.30, reflex action in left leg in six seconds, in right leg in ten seconds; 11.20, reflex action in both legs in thirteen seconds.

When the abdominal aorta had been ligated previous to the administration of the drug, no modification in the reflex function was observed upon the lower extremities.

If the alcohol is applied locally to the nerves, in small doses, the same slight increase of excitability is noticed, as proved by the experiment that follows, example of many others performed:

*Experiment 3.*—Destroyed cerebrum of a large frog and exposed the right sciatic nerve. After shock had passed off, a feeble current of electricity applied to the nerve-trunk by means of a Dubois-Reymond apparatus produced, at fifteen cubic centimetres between coils, contraction of the tributary muscles. At 9.45 A.M. gave 5 drops of alcohol subcutaneously. 10.15, distinct contractions of the muscles are elicited at twenty cubic centimetres between coils; 10.25, the same result at thirty, at thirty-five, and at forty cubic centimetres between coils.

These results are confirmatory of those previously obtained by Mommsen.\* This investigator found that alcohol, when brought in contact with them, distinctly increased the excitability of the peripheral motor fibres.

On the other hand, there is no doubt that large and toxic doses of the drug cause depression and paralysis of the peripheral nerves. I have frequently observed that, after death of frogs killed by alcohol, the nerves respond to electrical stimulation very slightly or not at all, these variations depending upon the quantities of the drug used. Wood† has found that the vapor of alcohol is capable of producing the

stupor known as anæsthesia, and, further, that this anæsthesia may be deepened into death, accompanied by all the phenomena of fatal ether narcosis. The following experiments explain themselves:

*Experiment 4.*—Large frog. Injected hypodermically 5 cubic centimetres of a twenty-five-per-cent. solution of alcohol at 1.20 P.M. 1.30, the animal shows no disposition to move about; respiration slow; apparently in a stupid condition. 1.45, movements exceedingly sluggish; greatly diminished reflexes. Died eventually from respiratory failure. After death, nerves and muscles respond weakly to electrical irritation.

*Experiment 5.*—Destroyed brain of a medium-size frog, and, after shock had passed away, tested reflexes by means of acidulated water. Reflex action was manifested in ten seconds. Gave, at 1.50 P.M., 5 cubic centimetres of a twenty-five-per-cent. solution of alcohol. 2.00, reflex action in fifteen seconds; 2.10, reflex action in twenty-five seconds. The reflexes continued to diminish until they were finally abolished. Similar results have been obtained by Dogiel,‡ who found the reflex susceptibility at first somewhat, and afterwards decidedly, decreased by large amounts of alcohol, and that the same effects of depression were produced on both the motor and sensory nerves.

Again, there is scarcely any doubt that in large quantities the effects produced by alcohol on the peripheral nerves are accompanied by alterations in the nerve-tissue itself, and both in the gray and the white substance. In regard to the latter, and particularly in reference to the peripheral nerve-filaments, the results of experimentation show this to be the case. It could not, indeed, be otherwise, judging from the very decided action of the drug. Thus, Jackimoff§ has made, in the laboratory of Merzcfewski, an experimental study of the nervous changes following the action of alcohol. The author divided his research into three series, giving the drug to puppies and dogs in the strength of forty per cent. The alcohol was administered, in the first series, in gradually ascending doses of from 1 to 8 cubic centimetres (16 grains to 2 drachms) for each kilogramme of the animal's weight, until death was produced. In the second series, the author so gave the drug, during the period of a month, as to produce an acute intoxication, which resulted in the death of the animal; while in the

\* *Archiv f. Patholog. Anatom.*, Bd. lxxxiii. S. 243.

§ *Bull. de la Soc. d'Anthropologie de Paris*, tome vii. p. 72, 1890.

third series of experiments an acute drunkenness was caused.

There was observed, resulting from the first series of experiments, a gradual paralysis of the hind legs, preceded by languor, muscular relaxation, accompanied with general hyperæsthesia and tenderness of the nerve-trunks. Death was caused in from five to eight months. No post-mortem lesions were observed in any of the organs, and, singularly enough, nothing abnormal was exhibited by the peripheral nerves under the microscope, while changes in other portions of the nervous system, as will be noticed presently, were distinctly seen. Why changes in the nerves were not observed, as in other parts of the nervous system, is not clearly made out, and can only be explained by some error committed in the microscopical examination. In fact, Jackimoff himself seems to admit this latter issue, since changes in the trophic cells could not occur without producing atrophy of the tributary elementary fibres. When the animals received the drug according to the second method, similar changes, although to a less degree, were observed.

Spaink\* has studied and endeavored to determine the action of ethylic alcohol, when given for a long time, particularly upon the peripheral nerves. He used in his experiments rabbits, and injected the drug, well diluted, by means of an œsophageal sound. Immediately after the death of the animal, the auricular, the tibial, and the pneumogastric nerves were taken out. These the author placed, for hardening purposes, in either Fleming's or Erlich's liquid, some of the nerves being stained by means of various reagents. The investigator was thus able to determine the degeneration of peripheral nerve-fibres, and found an especial modification of the axis-cylinder,—that is, a spiral twisting of this element corresponding, probably, to the direction of the degeneration of the fibre.

*On the Higher Nerve-Centres.*—That alcohol exerts a powerful influence upon the brain and other centres is a well-known fact, and needs neither further experimentation nor discussion. It may be said, nevertheless, that mild doses of the agent produce a primary stimulation of the cerebrum, and thus increase the rapidity, although perhaps not the depth, of thought. Upon the spinal cord, as well as upon the muscles and nerves, alcohol augments the reflex activity. Large amounts cause a loss of co-ordinating power, this being the result of

an action upon the brain and the lower nervous system. Under such circumstances the power of touch is partly destroyed, and it has been found that this loss of co-ordination is mainly due to paralysis of sensory function. Thus, Kraepelin,† in an especial research on the cerebral action of certain medicaments, has found that alcohol in small doses impairs the sensory functions and excites the motor ones; and that, on the other hand, in large amounts the drug first aids the motor processes and finally abolishes them. The loss of co-ordination “makes a drunken man,” as Hare‡ has so tersely expressed it, “fail to recognize the surfaces of obstructions, and the impaired mental power and disordered judgment, combined with the badly-acting motor and sensory pathways, cause him to stumble and fall.”

As in the case of the peripheral nerve-fibres, alcohol produces lesions of the brain, spinal cord, and the corresponding membranes. Jackimoff§ observed that if the constant acute intoxication of the third stage or series of his experiments were persisted in, death took place in from thirty to thirty-two days, and the post-mortem examination disclosed the lesions just mentioned. The microscope revealed great hyperæmia of the gray matter of both brain and spinal cord, extending into the adjacent white substance. It was noticed that in all instances the degeneration was an ascending one, decreasing in severity, however, as it proceeded. The chief lesion was found in the lumbar enlargement of the medulla spinalis.

#### ON THE CIRCULATION.

The influence which alcohol exercises on the circulation is extremely interesting and of the utmost importance. Without putting aside the study of the actions of the drug on other parts of the system, it is my purpose to make a special and thorough investigation of its influence on the circulatory apparatus, from the fact that in this there exists a great deal of contradictory evidence. I will, then, examine the literature of the various observations made so far, and afterwards discuss the results of my own experiments.

Quite recently Gutnikow|| has undertaken a series of experiments on curarized dogs. To these animals, under such conditions, he administered alcohol in ascending doses. The results obtained led the author to the follow-

ing conclusions: 1, alcohol produces a diminution of the arterial pressure, due to a depression of the vaso-motor centres; 2, the drug enhances the work of the heart; 3, it does not influence the pneumogastric nerve.

In the sphygmographic studies made by Parkes and Wallowicz\* on healthy men, it was found that the pulse was increased in both force and rapidity, but no distinct indications of increased blood-pressure were seen. Zimmerberg† states that alcohol reduces both the rate and force of the pulse, and that after division of the pneumogastric nerves the force and rapidity remain the same, but the arterial pressure is diminished. This author employed toxic doses, his experiments being made on animals. Dogiel,‡ who used small quantities, has observed at first an increase of cardiac rate, followed by a decrease of the same. The pressure was also raised from the beginning, then diminished, accompanied during this stage by a secondary increase of the pulse-rate; and he further noticed that under this latter condition the vaso-motor centres were paralyzed, since they did not respond to stimulation. He believes that the accelerator fibres (?) are stimulated. The author, unfortunately, does not detail his experiments.

Castillo§ obtained similar results in his experiments performed on frogs and rabbits. In these latter animals he found small doses of alcohol to produce a marked increase of the arterial pressure, followed by a distinct fall, especially when the dose of the medicament was augmented. The pulse was likewise increased in rate and force. These phenomena were not prevented by previous section of the vagi, of the accelerator nerves, or of the spinal cord. The author, therefore, concluded that the changes described were due to a direct action of alcohol upon the cardiac viscus. These statements appear to be further corroborated by the results of his experiments made upon the isolated heart of the batrachian.

Martin,|| from the results of an extended series of experiments, arrives at conclusions almost diametrically opposed to those of the investigators above referred to. His research was carried on with a view to ascertain especially the action of alcohol upon the heart of the dog. He isolated the organ by quite a complicated method,—a method invented by himself. The

experimenter used different strengths of alcohol, and found that blood containing one-eighth per cent. of the drug by volume had no immediate action on the isolated heart, that blood containing one-fourth per cent. diminished within one minute the work done by the heart, and that blood containing one-half per cent. of alcohol always diminished the work of the heart at once. It was observed that if the pericardium be cut away, this procedure prevented the action of even one-half per cent. of alcohol. The author ventures to explain this phenomenon by stating that alcohol so relaxes the cardiac muscle that there is no room in the pericardium for a full diastole, the relaxed heart being, even in its systole, about sufficiently large to fill the pericardium.

Hemmeter,¶ employing Martin's method of experimentation, has obtained similar results. He found that the work of the isolated heart of the mammalian is distinctly lessened by alcohol.

The more recent studies of Eagleton\*\* do not confirm the results of Martin and Hemmeter. Eagleton, by a continuous injection of alcohol into the circulation, found that small doses, frequently repeated, increased both cardiac force and arterial pressure; that large amounts at first increased, then diminished, blood-pressure, followed by a partial rise to the normal height, and, finally, by a progressive fall of pressure until the occurrence of death; that at the same time the frequency of the heart's beat is at first decreased, though there is sometimes a primary increase; that the pulse then partly returned to the normal rate and was subsequently decreased. He also found that strong alcohol, in minute quantities, generally increased the cardiac force and the pulse-rate. On the other hand, large amounts of alcohol decreased at once the rate and the force of the cardiac beat, accompanied by a diminution of the blood-pressure. These phenomena were the result of a direct action of the drug upon the heart, since they were observed similarly after the organ had been previously isolated from all nervous connection. Therefore the author concluded that alcohol, in small doses, is a cardiac stimulant; in large amounts, a cardiac depressant.

Eagleton, then, agrees with the observations of most previous experimenters, with the exception of Martin and Hemmeter, and his results sustain the common clinical belief that

small amounts of alcohol increase the force of the circulation.

Meissner,\* who experimented on mice and rabbits with allylic alcohol, has shown that this substance produces violent irritation of the mucous membranes, accompanied with great dilatation of the blood-vessels and consequent lowering of the arterial pressure. In his experiments death was caused by allylic alcohol through respiratory failure, preceded by dyspnoea and convulsions. Narcosis, however, was not produced by this agent.

An interesting study of the actions of the alcohols belonging to the ethylic and aromatic series has been published by Gibbs and Reichert.† The authors examined propylic, isopropylic, butylic, iso-butylic, heptylic, octylic, allylic, benzylic, and cuminic alcohols. The results of their experiments upon animals show that the actions of these various substances are essentially of the same character, though differing in degree. Ethylic alcohol, which may be taken as a type of the ethyl series, was carefully studied, and its actions on the circulation and the respiration are thus summarized: Small doses increase the frequency and force of the cardiac beat, increase the arterial pressure, and increase the respiratory movements. Large doses generally decrease, but sometimes increase, the pulse-rate, primarily increase and then lower the arterial pressure, and increase the respirations. Very large doses depress the pulse, pressure, and respiration. The changes in the heart-beat are due to direct actions on the heart; the increase of pressure is also due to a direct action on the heart. The decrease of pressure is due to a depression of both the heart and vaso-motor apparatus. The primary increase and final decrease in the respiratory rate are due to a stimulation and subsequent depression of the respiratory centres. The authors are led to believe that the action of the other alcohols is identical with those of ethylic alcohol, the differences being essentially in degree, and increasing with the acquisition of each radicle; in other words, the higher the alcohol in the series the greater its toxic power. The actions of the benzylic and cuminic alcohols, which belong to the aromatic series, are apparently the same as those of the others.

It must be admitted that many observers have seen depressant effects caused by alcohol, even when ingested in small quantities. It will be sufficient for me to mention the

names of Lauder Brunton, Hammond, Hervier and Saint-Layer, Fife, Lehmann, Perrin, Richardson, Smith, and Vierordt, the work of all of whom has been examined and reviewed by MacDowel Cosgrave.‡ In all these studies it is stated that alcohol produces from the first a narcotic rather than a stimulating effect.

The statements made by these latter high authorities deserve certainly serious consideration; yet, I believe, the scale of experimental evidence is inclined towards a stimulation rather than to a narcosis produced by alcohol, especially when moderate amounts of the drug are judiciously used.

I will now examine the results of my own experiments, studying the effects of alcohol on the pulse, both of the isolated heart of the frog and that of the dog, and upon the blood-pressure *seriatim*. The warm-blooded animals used by me in the experiments to be presently described were exclusively dogs.

*On the Heart.—The Pulse.*—I prepared different solutions of alcohol, of the strength of .5, 1, and 2 per cent. respectively. In these solutions I placed the isolated hearts of frogs, and compared their activity with that of others placed in simple solutions of chloride of sodium. For example, two hearts were placed first in the salt solution, and their beats counted. One of the hearts was then taken out carefully and placed in the alcoholic solution, alongside of the other, and their beating carefully observed. I will detail the following experiments:

*Experiment 6.*—In this experiment the hearts were beating at the rate of 48 per minute.

Alcohol Solution, 5 Per Cent.		Chloride of Sodium, Normal.

1.25	20
1.35	8
1.46	Arrested.

In Experiment 6 the pulse was increased 10 beats above the normal within a short time, and thus continued, with slight variations, for a period of twenty-five minutes; the pulse then returned to normal, and was afterwards decreased gradually until the heart was finally arrested in diastole.

The same results, although to a less marked degree, were observed when one- and two-per-cent. solutions of alcohol were used, as in Experiments 7 and 8. In these an increase of 18 and 12 beats per minute, respectively, was also noticed, lasting for about twenty minutes. The pulse then gradually began to decrease until its final cessation, this occurring in about thirty-eight minutes longer. In both experiments the heart continued to act in the salt solution for a longer time (from eighteen to thirty-five minutes), but at no time was there an action above the normal produced.

A very dilute solution of alcohol—say .1 per cent.—has no perceptible action upon the pulse, as is shown in the following record:

*Experiment 9.—**Alcohol Solution,  
1 Per Cent.*

Time.	Pulse.
10.40	62
10.45	60
10.50	58
10.55	52
11.05	40
11.15	32
11.20	8
11.28	Stopped.

11.06	58
11.18	50
11.25	16
11.30	16
11.35	12
11.48	Stopped.

It is thus observed that, although very dilute alcohol does not apparently influence the action of the heart of the frog, small amounts do increase the rapidity of the cardiac beat, this phenomenon being eventually followed by a depressant effect. Large doses diminish from the first the pulse-rate.

The same effects—that is, those of stimulation by small doses and of depression by large or toxic quantities—are observed in the heart of the dog. In these instances I have employed the drug in repeated doses, at short intervals or in continued injection, following the method of Eagleton. The agent has been used in the strength varying from twenty to twenty-five per cent. In this manner coagulation of the blood was prevented to a very large extent.

In all these experiments the drug was injected into the general circulation through the external jugular or internal femoral vein, while the carotid or femoral artery was connected with the recording kymograph.

It will be seen from the appended experiments, numbered 10, 11, 13, 14, and 17, that small doses of alcohol increase the rapidity of the pulse. This increase is usually accompanied by a corresponding rise of the arterial pressure. If during the experiment an electrical current is applied to the central or peripheral end of a cut vagus, inhibition of the heart is immediately produced (see Experiment 13), a fact of great significant importance.

I shall now proceed to study how this rapidity of the pulse is brought about. As in the case of normal animals, in curarized dogs small doses of alcohol, ingested at short intervals, cause an increase in cardiac rate. In larger amounts, however, there is sometimes an increase, followed by a decrease; sometimes a diminution from the onset, followed by an increase and then by a decrease; while in either instance the blood-pressure is raised, some-

times remains unaltered, or falls if the dose of the agent be sufficiently toxic. The effects on the arterial pressure in curarized animals I will discuss later.

I find that the same stimulating effect upon the cardiac beat is caused by small doses of alcohol when the pneumogastric nerves have been previously divided, and similarly when the cardiac viscus has been isolated from all nervous connection by previous section of both vagi and of the spinal cord.

An examination of Experiments 18, 19, 20, and 21 will sustain these statements.

A careful examination of all these experiments shows that there are no marked changes in the pulse-rate in connection with the variations of the blood-pressure, except those due to a direct cardiac action. Again, there is, indeed, no evidence to the effect that the vessels themselves are any way altered in size by alcohol. Moreover, the results obtained in the experiments performed on the isolated hearts of frogs point to one and the same evident conclusion.

Alcohol, then, in small amounts, causes an increase in the pulse-rate, not by influencing the cardio-inhibitory apparatus or the vaso-motor system, but mainly by a direct action of the drug upon the heart. These results confirm those obtained especially by Castillo and Eagleton.

Large quantities of alcohol, on the other hand, exercise from the beginning a depressant effect on the rate of the pulse, this phenomenon continuing till the occurrence of death, and it is safe to infer that such an effect is similarly the result of a direct cardiac action.

(To be continued.)

#### THE ANTISEPTIC PROPERTIES OF THE OIL OF CINNAMON.

BY D. BRADEN KYLE, M.D.,

Laryngologist to St. Agnes's Hospital; Bacteriologist to the Orthopaedic Hospital and Infirmary for Nervous Diseases;  
Assistant Demonstrator of Pathology and  
Instructor in Clinical Microscopy,  
Jefferson Medical College.

SINCE 1869, when Lister announced his antiseptic method, the medical profession has been searching for the best and safest antiseptic.

Many have been launched upon the profession only to be wrecked by the laboratory investigations of the bacteriologist and the clinical test of the surgeon. Bichloride of mercury, while a dangerous antiseptic, has stood the test better than any other which has been introduced; but from its poisonous properties it

cannot be used on surfaces which rapidly absorb fluids, as the peritoneum, or, if used, must be flushed immediately with boiled water.

As the abdomen is the field of a large proportion of surgical operations, this is an unquestionable hinderance; the same may be said of its use in the pleural and brain cavity. Another great disadvantage is its action on the instruments, necessitating their special disinfection.

The antiseptic method introduced at Johns Hopkins Hospital, of oxalic acid and permanganate of potassium, while good, has many disadvantages to the surgeon. The discoloration of the hands is one of these, and, it being a colored fluid, the instruments cannot be placed in it on account of the surgeon not being able to locate them.

As science is always progressive and the field open for investigation, we beg leave to report the results of experiments with another antiseptic, which, while not new, has not yet been thoroughly investigated. It is a well-known fact that the essential oils possess marked antiseptic properties. I have used in my private and hospital practice the Ceylon oil of cinnamon, in the treatment of infective varieties of nasal, laryngeal, and aural affections, with marked success, which led me to believe that the oil possessed antiseptic properties, and this in turn, led to further investigations.\*

The antiseptic properties of this drug have long been known. Even among the laity the water obtained by soaking the bark is known to possess healing properties.

In 1670, Hoechstetterus made mention of the healing properties of the oil. Titus in 1707, Goller in 1709, and Gehler in 1787.

One hundred years later, Chamberland, in the "Annales de l'Institut Pasteur," vol. i. pp. 153-164, reports his observations as to the antiseptic properties of essence of cinnamon, in which he states that "no living germ of disease can resist the antiseptic power of essence of cinnamon for more than a few hours." He claims that it destroys the microbes as effectually, if not as rapidly, as corrosive sublimate.

Championnière, in an article in the *Journal de Médecine et de Chirurgie Pratiques*, June 10, 1893, mentions the antiseptic properties of the oil of cinnamon and recommends its use as a

\* These investigations were carried on in our private laboratory, dating back to October, 1892, from which date to the present Dr. J. Chalmers Da Costa and myself have conducted these experiments both from a practical and theoretical stand-point, and our thanks are due to Mr. John Johnson, surgical clinic nurse in the Jefferson College Hospital, for preparing the solutions.

dressings for wounds. He also claims that the irritating action can be avoided by adding retinol to the solution. When the Ceylon (pure) oil of cinnamon is used, the irritation is reduced to the minimum.

To test its antiseptic properties, pure cultures of different germs were used, the oil of cinnamon being of the strength of 1 to 500. It was found on exposing the cultures, kept at a temperature of from 60° to 98.6° F., that, after from thirty minutes to two hours, inoculations made from these tubes, with few exceptions, showed no growths, even when incubated; the germs of suppuration and erysipelas were destroyed in not less than thirty minutes, while those of tubercle, anthrax, tetanus, and glanders required exposure of at least two hours; typhoid fever less than these, but over one hour. The germ of Asiatic cholera, while markedly resistant, was found to show no growths after from three to five hours.

The hands were first cleansed by means of soap, water, and brush, finger-nails cleaned, and then the hands bathed in the 1 to 500 cinnamon solution. Four tubes were inoculated from the hands,—two from under the nail, and two from the surface of the skin.

From these no growths were obtained; but on repeating the experiment, one tube out of four (inoculated from under the finger-nail) showed a mixed growth, from which the germs of suppuration were isolated.

How oil of cinnamon acts in these vegetable cells, the following theory may explain: The germ being an albuminous compound, composed mainly of nitrogen, oxygen, and hydrogen, and being enclosed in a capsule of varying thickness, the chemical composition of which is cellulose, when brought in contact with the active principle of the oil, the cinnamic acid, has its cell-wall contracted, which practically deprives the germ of its nutrition. By microscopic examination this theory is confirmed.

The results obtained would lead one to the conclusion that this is a germicide, but there is a vast difference between laboratory and clinical antiseptics and germicides.

The germ, when transferred from the tissue to the artificial media of the test-tube, even in the most virulent cases requires several days to accommodate itself to its environments,—its *hygiene*, it might be called.

The solution which will act on this now *laboratory* germ will not always act with such good results when the germ is in its natural •nidus. It is the writer's belief that the drug is an antiseptic which only retards the growth of the germ by its action on the capsule, and

that the germ recovers its activity before the process of healing can take place.

The action of antiseptics and germicides on pure cultures of germs is largely controlled by the generation of the germ, having more effect on those which have reached the fourth or fifth generation. This will often explain the difference in results obtained by different experimenters.

In all the cases where the solution of oil (1 to 500) was put to the clinical test,—those under the care of Dr. Da Costa,—the wounds healed by first intention. In one case in particular, where the incision was at the inner angle of the eye, where the secretions from the lachrymal duct always retard the healing process, the union was uninterrupted. In the cases where it was used in abdominal work the results were not so good, as in three out of four infection occurred; yet, at the same time, in many cases in which the bichloride of mercury was used the same bad results have been obtained. This refers more to the connective tissue and serous membranes, while on mucous membranes clinical experience shows that it possesses marked germicidal properties.

Da Costa, in his article on the treatment of gonorrhoea by hydrogen dioxide and oil of cinnamon, published in the *Medical News*, October 21, 1893, shows what good results he obtained, while the writer has used it for over two years in the treatment of various nasal, laryngeal, and aural diseases with success. The conclusions, then, to be made from the laboratory and clinical investigations are, that the oil of cinnamon is not a safe antiseptic for surgical work, but that it is a good mucous membrané antiseptic, and, contrary to the conclusions of Chamberland and Black, I do not believe it to be a germicide.

1632 CHESTNUT STREET, PHILADELPHIA.

**ENORMOUS OVAL HEMORRHOID ENCIR-  
CLING THE ANUS; WHITEHEAD'S  
OPERATION; ENTIRE CURE.**

READ BEFORE THE SECTION ON SURGERY OF THE COLLEGE  
OF PHYSICIANS OF PHILADELPHIA, MARCH 8, 1894.

By W. W. KEEN, M.D.,

Professor of the Principles of Surgery and of Clinical Surgery in  
the Jefferson Medical College.

REV. DR. E., aged sixty, was brought to me at the Jefferson Hospital by Dr. J. T. Rugh, December 4, 1893. There is marked tuberculosis and insanity in the family; he had enteric fever in youth and several attacks of dysentery; has always been markedly constipated. He has had trouble with hemorrhoids and prolapse of

the rectum for about thirty years. For the last twenty years it has been a serious disability, and for the last two years it has practically prevented his doing any work in his profession, or, in fact, work of any kind whatever. He has scarcely begun his service in the pulpit before protrusion of the mucous membrane and the hemorrhoids takes place, and his discomfort is so great that he is unable to preach. Seven years ago he consulted the late Dr. Agnew, who advised him, in view of the severity of his condition, not to have any operation done. He has lost large amounts of blood of late, and never has a stool without the protrusion.

*Status Præsens.*—A well-nourished, large, heavy man. On examining the anus, it resembles more than anything else a large, swollen vulva after delivery (Fig. 1). It measures four inches long by three inches wide, the outer margin being one enormous, oval hemorrhoid about an inch and a quarter in diameter and surrounding the anal aperture as though it were a great oval piece of rope. The aperture of the oval is filled with the prolapsed and ulcerated mucous membrane.

*Operation, December 9, 1893.*—I began the operation posteriorly by an incision, which finally encircled the entire anus, at about the middle of this marginal hemorrhoid. In doing so it was very curious to notice how the fibrous tissues, being put on the stretch, were divided, but the softer, dilated hemorrhoidal veins yielded before the sharp knife without being cut; the moment that there was an aperture, the dilated veins would form herniæ of large size between the fibres.

I first went directly towards the anal aperture until I recognized the sphincter muscle; then by a blunt dissection of the tissues I reached the mucous membrane on the inner border of the sphincter. Following this, two fingers were inserted into the calibre of the rectum, and the pile-bearing area seized between the thumb and palm. The moment I recognized the mucous membrane at one point, from that as a point of departure I proceeded with the blunt dissection, all the way around, with but little trouble. Only three ligatures were required, and the amount of blood lost was moderate,—nothing whatever of a severe character. The operation, which had looked most formidable before it was begun, was quickly performed with comparative facility. The whole pile-bearing area was cut away, step by step, and the mucous membrane stitched to the skin *pari passu* with the cutting. When the operation was finished the anus was little more than its normal size.

After the operation the patient reacted well, without nausea. The wound was dressed with careful antiseptic precautions. His highest temperature was 101° F., which was only reached once, on the third day, and again on the eighth day, in consequence of constipation. With these exceptions, the temperature ran from 98.5° to 100° F. He was perfectly comfortable almost from the moment when the operation was completed. On the third day his bowels were opened by an enema of sweet oil and citrate of magnesia by the mouth. He had but little control of the sphincter muscle. On the eighth day the stitches, which had begun to cut out, were removed. Union by first intention took place, excepting at two small points, where the mucous membrane and skin gaped a little. He was out of bed in two weeks, and went home in three weeks, perfectly comfortable. The gaping points were not quite healed. He was directed for a year to keep the bowels in a soluble condition by means of enemata and laxatives, and whenever possible to have his bowels evacuated in a bed-pan in the recumbent position. His control over the sphincter had returned almost entirely by the time that he left the hospital.

*Remarks.*—The case is quite exceptional, in my experience. I have never before seen such an enormous pile encircling the anus,—four inches long and three wide. I confess that when I first saw him I was not a little in doubt as to what ought to be done. The result has shown that the Whitehead operation was not only the best thing to do, but I think the only thing.

Since he left the hospital I have heard from him repeatedly and always with the most favorable report. Since the middle of January he has preached every Sunday, sometimes three sermons in a day, has done pastoral work, travelling as much as twenty miles, and at home splits kindling-wood, carries coal, shovels snow, and can walk several miles without any fatigue. The result leaves nothing to be desired.

#### BISMUTH SUBGALLATE (DERMATOL) IN DERMATOLOGY.

By J. ABBOTT CANTRELL, M.D.,  
Professor of Diseases of the Skin in the Philadelphia Polyclinic  
and College for Graduates in Medicine; Dermatologist  
to the Philadelphia Hospital and to the St.  
Agnes Hospital, Philadelphia.

IT is said that the drug dermatol, a proprietary preparation, has been known for many years under the name subgallate of bismuth. It was first made known by Heinz and Liebreich (*Berlin. Klin. Wochenschr.*, 1891, No. 24,

p. 584), who state that it is a saffron-yellow, very fine powder, that it does not absorb water, and does not change in light or air; it looks like iodoform, but has this advantage over the latter, that it is odorless; it acts as an energetic, dry antiseptic; it is insoluble in most liquids; its antibacterial qualities are only exercised by direct contact, as, for instance, by its thorough admixture with the nutritive soil; this drying property, which is really an astringent quality, causes it to be particularly useful in the cure of wounds and ulcers.

Heinz (*Berlin. Klin. Wochenschr.*, 1891, No. 27) suggests that in excoriations, intertrigo, and slightly moist eczemas, this drug, mixed with an indifferent powder, is of use; for instance, bismuth subgallate, 20 parts; pulvis talcum, 70 parts; amyli, 10 parts. Over small abrasions or wounds a ten-per-cent. emulsion with collodium may be used. In extensive ulcers and so forth one of the following ointments is of use: No. 1. Bismuth subgallate, 10 to 20 parts; petrolatum, 90 to 80 parts. No. 2. Bismuth subgallate, 10 parts; lanolin, 80 parts; vaseline, 10 parts. According to these conclusions, Heinz states that the drug is not indicated in torpid ulcers (chronic ulcers of the leg), where a stimulating treatment is indicated. The writer also suggests a gauze of ten-per-cent. strength.

Heinz and Liebreich have used it with success in one hundred cases, made up of burns, eczemas, ulcers, and affections of the eye, ear, and nose, without producing any poisonous or irritating effect. They state that it favors the growth of granulations, and consequently the process of cure; also that while iodoform brings on secretion, the subgallate of bismuth hinders its formation.

Rosenthal (*Berlin. Klin. Wochenschr.*, 1891, p. 728) confirms the results of Heinz and Liebreich, but instead of the formula (bismuth subgallate, 10 parts; lanolin, 20 parts; vaseline, 70 parts) given by them, he prescribes the following ointment: Bismuth subgallate, 2 parts; pulvis zinci oxidi, 2 parts; petrolatum, 20 parts. He also suggests a paste of two or three per cent., which may take the place of the salicylic-acid paste, because, while irritating less, it has a more drying effect. It is composed as follows: Bismuth subgallate, 2 parts; pulvis zinci oxidi, 24 parts; amyli, 24 parts; petrolatum, 50 parts. Employed in this way, it is useful in some cases of eczema.

Rosenthal (Berlin Dermatological Society, July 7, 1891, and *Monatshefte*, vol. xiii. p. 209, 1891) investigated the antiseptic properties

against the *Staphylococcus pyogenes albus* and other bacteria, and found it to be almost useless, excepting in large quantities, and in this respect it is very much like aristol. The writer (Rosenthal) is rather doubtful as to its permanent value in eczema, but as a dressing after the opening of furuncles it acts favorably.

The general opinion of dermatologists at the meeting at which the paper of Rosenthal was read was, that the drug resembled very much the subnitrate of bismuth in most therapeutic properties, but that it has a little more action.

A. Bluhn (*Therapeutische Monatshefte*, Berlin, 1891), who also investigated its effect upon bacteria, has found it active against the following micro-organisms: *Staphylococcus pyogenes albus*, *Staphylococcus pyogenes aureus*, and a number of others.

In all cases the drug prevented the growth of the micro-organisms, and in some it destroyed them.

Clinically, he found the drug useful in eight cases of ulcer cruris, producing satisfactory results in all of them. In one case it replaced iodoform, which was not well borne; also one case of carbuncle was healed.

Sachur (*Berlin. Klin. Wochenschr.*, 1891) says that bismuth subgallate, used in the treatment of ulcers, keeps the parts free from the eczema that is so often produced by irritating discharges, and that it is the best remedy in non-syphilitic leg ulcers.

Doernberger (*Therapeutische Monatshefte*, 1891) found it useful in moist and impetiginous eczemas of children. It was not, however, effectual in preventing the development of papular eczema. Abscesses, first incised and then treated with the powder, healed rapidly. He recommends it used in the form of ointment of ten per cent. with vaseline or a ten-per-cent. gauze.

Guirard and Cadeac (*Lyon Medical*, Lyons, May 8, 1891) find it to give good results in the humid eczemas which, in the dog, are generally of a rebellious nature, and upon which it exercised a desiccant and astringent action.

Asch, of Breslau (*Provincial Medical Journal*, Leicester, England, April 1, 1891), found that in cases of eczema caused by or occurring during the use of certain antiseptic dressings it acted quite efficaciously.

Azua, of Madrid (*Revista de Medicina y cirugía practicas*, Madrid, March 7, 1891), says that it dries bleeding surfaces and stimulates granulations, and is particularly useful in skin-diseases characterized by much discharge,

although he was unable to confirm its antiseptic properties.

Weismüller (*Berlin. Klin. Wochenschr.*, 1891, p. 1201) has used it in seven cases of leg ulcer without beneficial results. He has also found unpleasant symptoms in a like number after the use of it by external applications, as follows: In one case thirty grammes had been used during twelve days as a dusting-powder for an ulcer of the foot, when vertigo and severe itching ensued; in another case an itching eruption broke out over the whole body; five other cases were similarly affected after the use of the drug.

Glaeser (*Berlin. Klin. Wochenschr.*, 1892, No. 24) says that the cause of poisoning can be explained, because arsenic formed a portion of the powder used. Glaeser, in an extensive experience with the drug in the last year and a half, noticed in one case icterus and diarrhoea in another, but both got well, although the drug was continued. Glaeser considers it perfectly harmless.

H. Isaac (*Deutsche Med. Wochenschr.*, No. 25) recommends it in intertrigo of all kinds, especially in that kind caused by perspiration around the anus and mammæ. In fissures of the nipple, Isaac uses a two-per-cent. solution of nitrate of silver as a caustic, and subsequently bismuth subgallate. In acute moist eczema the powder often causes quick cure. In dermatitis caused by antiseptics like iodoform and mercury bichloride it cures quickly. In abrasions and fissures it seems to promote the formation of epidermis.

Werther (*Deutsche Med. Wochenschr.*) considers that the drug never acts injuriously to the skin or to the general system. He thinks it better than iodoform, because it has no toxic effect. Werther praises it for its astringent and antiseptic effect, as also for its freedom from odor and poisonous effect.

Stierlin (*Correspondenzblatt für Schweizer Aerzte*, Basel, November 7, and *Provincial Medical Journal*, Leicester, England, 1892) summarizes as follows: 1. It is perfectly free from any toxic properties. 2. It never gives rise to eczema or any other signs of local irritation, such as are frequently caused by iodoform. On the contrary, powdering with the bismuth subgallate affords the best means for speedily curing the iodoform exanthemata. 3. It powerfully absorbs wound secretions, and proves exceedingly useful in all cases where astringents and drying are desirable. Thus, it is good in small-sized, non-septic wounds which are more or less shallow. It acts well in burns and scalds of the second

degree. Blisters should be opened and dusted with the dry powder directly to the raw surface. 4. Cotton-wool should not be placed directly over it, because it may stick to the dressing and be removed with difficulty. 5. It should never be used in infectious suppurating wounds (furuncles, etc.), since its application may lead to dangerous retention and accumulation of pus under the crust thus formed. 6. It is useful in large crural ulcers, in moist eczema, and intertrigo. 7. In tubercular ulcers and fistulæ it is inferior to iodoform; it does not possess the antibacterial action of the iodoform. 8. Its antiseptic properties are weak; it is limited to drying tissues, and thus depriving bacteria of a suitable medium for their development.

A. Schmitt (*Revue Médicale de l'Est*, Nancy, France, March 15, 1892) and Schtschegolow (*Chirurgilcheskij Westnik*, St. Petersburg, October and November, 1892) also accord insignificant antiseptic properties to the drug. It is inferior to iodoform in this particular.

Fischer (*Druggist's Circular*, August, 1892) says that it can be made as follows: Bismuth subnitrate, 15 grains, dissolved in 30 parts of glacial acetic acid; 200 or 250 parts of water are added, and then the mixture filtered. To this mixture is added, with constant stirring, a warm solution of 5 parts of gallic acid in 200 or 250 parts of water. An insoluble precipitate is formed, which is first to be washed by decantation and then filtered until the washings give no trace of nitric acid. This is then to be dried at 100° C. (212° F.), and the powder thus prepared should be insoluble in alcohol, showing the absence of gallic acid, and should show the presence of not less than fifty-five per cent. of bismuth oxide, the theoretical amount in the compound being 36.66 per cent.

C. A. Power (*New York Medical Journal*, August, 1892) says that it is odorless, non-irritating, and non-poisonous. It is said to give good service in pemphigus and herpes zoster.

A. K. Stone (*Boston Medical and Surgical Journal*, September 1, 1892) says that it has active powers of hindering the growth of bacteria, but that it is not bactericidal.

P. Grossman (*Omaha Clinic*, October, 1892) uses it with an equal quantity of castor oil in sore nipples. As the drug is not toxic, it is not necessary that the breast be thoroughly cleansed before the child receives its nourishment.

Allen (*Medical Record*, No. 42) says that the drug is insoluble, non-toxic, and non-irritating to the skin. A two-per-cent. ointment cures

burns of the second degree; a plaster will prevent the pits of small-pox.

Wicke (*Intern. Klin. Rundschau*, 1893, No. 5) has observed that the drug, mixed with nitrate of silver, acts as a caustic on open wounds without giving pain. (If this be so, it is an unfortunate thing that the writer did not give the quantities used.)

Mattheus (*Therap. Monatsch.*, 1893, No. 8) has observed, after using the subgallate of bismuth in certain ulcers of the leg, a severe inflammation of the surrounding skin appearing at the end of the first or beginning of the second week. The affected part was red, hot, and exuded a serous, watery fluid.

The clinical experience of the present writer is not as extensive as some of those cited above, yet it is sufficient to base conclusions on, as the following cases will show:

*Intertrigo*.—Of contiguous portions. Three cases dusted with the following powder: Bismuth subgallate, 15 grains; pulvis amyli,  $\frac{1}{2}$  ounce. Patients returned on the following day, and it was found that the parts were somewhat more inflamed. The treatment was changed in all three cases to dustings of lycopodium powder, and patients were decidedly relieved.

*Ecsema Vesiculosum*.—Dorsal surface of fingers of both hands.

March 9.—Bismuth subgallate, 10 grains; petrolatum,  $\frac{1}{2}$  ounce; which was to be applied twice daily and bandaged.

March 12.—Patient returned, saying that the unguent had irritated the parts so much that he discontinued it after applying it twice (in twenty-four hours), and that the parts became swollen to almost double their natural size, discharged freely, while the cloths stuck to the denuded surface. To-day the parts are red, hot, and still discharging some serous fluid; the parts at points are denuded of epidermis, looking as though it had been acted on with a caustic.

*Ecsema Seborrhoicum*.—Patch (two inches square) over the nucha.

February 19.—Bismuth subgallate, 15 grains; vaseline, 2 drachms.

February 24.—Marked improvement; decidedly better.

*Ecsema Fissum*.—Back of hands.

February 9.—Bismuth subgallate, 15 grains; acidi borici, 1 drachm; ungt. diachylon,  $\frac{1}{2}$  ounce.

March 2.—Proved entirely too stimulating.

*Ecsema Squamosum*.—Boy, aged seven years; disease confined to both forearms; has lasted six months.

February 27.—Bismuth subgallate, 10 grains; vaseline, 4 drachms.

March 3.—Improved.

March 6.—Improved very much.

*Ecsema Rubrum*.—Of both legs; man, aged fifty-five; duration, three weeks.

March 5.—The same treatment as in the former case.

March 7.—Very much better; no itching at the present visit.

March 9.—Almost well.

*Ecsema Rubrum*.—Over the nates in a boy of four years of age; has lasted about one month.

March 8.—The same treatment as in the former cases.

March 12.—Very much better.

*Ecsema Rubrum*.—Man seventy years of age; disease confined to both legs for the last ten years; very much over the legs from the ankle to the knees; not moist.

February 8.—Treatment as in the foregoing cases.

March 14.—No improvement whatsoever; treatment changed.

*Ecsema Papulosum*.—Surrounding both wrists; lesions numerous, of two years' duration; has been under treatment in the clinic for some time, when, on the 6th of March, the treatment was changed to the following: Bismuth subgallate, 15 grains; petrolatum,  $\frac{1}{2}$  ounce.

March 11.—Patient returned to-day almost well.

*Ecsema Seborrhoicum*.—Covering the back from the shoulders to the buttocks, of ten days' duration, in a man of thirty years.

March 4.—Bismuth subgallate, 15 grains; petrolatum,  $\frac{1}{2}$  ounce.

March 14.—Man returned almost well.

*Ecsema Vesiculosum*.—Child four months of age; lesions have existed since birth; cover the right side of face.

February 19.—Bismuth subgallate, 5 grains; petrolatum, 4 drachms.

March 1.—Child somewhat improved; did not return after this date.

*Ecsema Vesiculosum*.—Of the face, just in front of the ear; lesion covered with a crust; very itchy.

February 19.—After removing the crust, the same treatment as in the former case.

February 28.—No improvement.

March 8.—The condition remains the same as at the first visit.

March 14.—The drug not proving serviceable, it was changed.

*Ecsema Rubrum*.—In a child of two years,

in whom the eruption had existed since birth; the disease was confined to the cheeks.

*March 6.*—Bismuth subgallate, 10 grains; vaseline, 4 drachms.

*March 10.*—Child very much better; in fact, almost well.

*March 14.*—Progressing as well as at the previous visit.

*Ulcer of Leg.*—Two cases,—one in a man of sixty years, the other in a woman of forty-five years; both found upon the leg, below and around the ankle; due to the varicose condition of the veins, each having some eczema surrounding the ulcer. Treatment as in the foregoing cases for the eczema, and the ulcer dusted with bismuth subgallate,  $\frac{1}{2}$  drachm; pulvis amyli,  $3\frac{1}{2}$  drachms. This treatment was carried out for two weeks without the slightest change in the ulcer, although the eczema was cured.

*Ulcer of Leg.*—In a man of fifty years and of four months' duration, being situated upon the outer side of the right ankle; decided varicosity of the veins in this region; slight eczema surrounding the ulcer.

*February 24.*—Bismuth subgallate,  $\frac{1}{2}$  drachm; pulvis amyli, 4 drachms; this to be applied to the ulcer twice during the day.

*February 25.*—Patient returned with the parts swollen, cedematous, and very painful, and were exuding great quantities of a serous fluid; the eczema was much worse, having spread to a much greater extent.

As we are often requested to give our professional views upon drugs of this class, and as I find that my experience is somewhat different from some of the reports of others, I have deemed it wise to give in detail all that has occurred while I have been using it. As the drug is inferior to others of the class to which it is claimed it belongs, I would willingly lay it aside now that I have found its defects, as the following summary will disclose:

#### SUMMARY.

1. The drug may not be toxic. I did not investigate this property, as I had occasion to use it externally only.

2. It is not superior to other iodoform substitutes, such as iodol and aristol.

3. It does not hinder discharge; on the contrary, it increases it.

4. It is decidedly irritating, as the foregoing facts will show.

5. It is a stimulant rather than an astringent; in fact, it acted almost as a caustic in one or two cases.

6. It cannot take the place that has been allotted to it.

7. I think we have more promising remedies.

#### ALCOHOLISM: THE TREATMENT AND CURE OF THE DISEASE.

BY CYRUS F. TAYLOR, M.D., PUEBLO, COLORADO.

THERE has been so much written and said upon this subject within the last three years that I fear an article from me at this time will prove uninteresting; but so much that has been written, it seems, has been theoretical instead of practical, that I am prompted to this communication.

That alcoholism is a disease, or that there is a diseased condition of the stomach, intestinal tract, circulatory system, brain, nervous system, etc., there is no longer any doubt, especially after the long and continuous or excessive use of liquor.

I recognize and have found it convenient to divide the disease into three classes,—viz., acquired, hysterical, and hereditary. In my opinion, there is a vast difference in these three forms, and some may question my authority for this classification, which I wish to say is based upon practice rather than theory. In this article I will give only one general outline of treatment, which can be varied to suit the class.

After having made a special study of alcoholism for more than two years, and having treated over two hundred cases myself, and about one hundred more having been treated under my instructions by Dr. W. H. Baker, I feel that perhaps the results of my experience may be of some use to the profession at large.

Ninety-five per cent. of such patients treated by us have been cured, and have remained so for a length of time varying from two years to the present.

The patient should be thoroughly examined; an examination of the urine should be made, and in all cases the condition of the heart and lungs should be observed carefully, and everything pertaining to the patient's past life and habits should be ascertained and noted before beginning treatment.

If the patient has been a constant drinker for years and is beginning treatment after a big "spree," the treatment should consist of strychnina nitratis, administered hypodermically four times a day at regular intervals,  $\frac{1}{100}$  grain, gradually increased to  $\frac{1}{80}$  grain, per dose, or until some marked physiological symptom, as twitching of the muscles or chilliness, is com-

plained of, when the dose should be decreased for a day or two, according to symptoms, or according to the patient's ability to stand large doses, or the need of large doses. I have found that patients suffering from alcoholism will stand about  $\frac{1}{10}$  grain three or four times a day for thirty or more days with no ill effects, as I have never observed any alarming symptoms from this part of the treatment, and that old inebriates begin to have an appetite for an early breakfast, and mend generally, within four or five days from the commencement of the treatment. To those acquainted with the action of strychnine upon the system the reason is obvious. Along with this and at the same time I give atropine sulphate, from  $\frac{1}{100}$  to  $\frac{1}{80}$  grain per dose, until marked physiological symptoms are produced. The atropine can rarely be continued over one week, sometimes not longer than three or four days, and in certain cases cannot be used at all, owing to the peculiar action of the drug upon the nervous system and stomach. One must be very careful not to use too much or for too long a time, and at the same time must thoroughly understand his patient and give enough and long enough.

It is better to discontinue the atropine early than to push it, for it can be easily taken up again at any time should the patient require it, and one not thoroughly versed in this part of the treatment should be careful lest alarming symptoms arise. However, I generally begin to decrease the dose of the atropine when the characteristic symptoms appear well marked, and not until then. I usually wait for the dryness of the throat and nose and that peculiar sick feeling at the stomach which old toppers call "squeamishness," the dry and suffused eyes, and the dilation of the pupil to such an extent that one cannot read ordinary print without the aid of glasses, and in exceptional cases not until marked head symptoms appear. I also give digitalis in most cases. That it is an excellent remedy to give with the two former I know from personal experience, and had I been aware of it sooner I might have been saved several nights' sleep. I also give a tonic in these cases. This is usually put up to suit the special case, but an excellent tonic is composed of the following: ext. cinchonæ fld., ammonii muriatis, and some preparation of digitalis or lily of the valley, although it is much better to use a tonic adapted to the particular case at hand, for a patient suffering from alcoholism is generally a sufferer from troubles of the nervous system, stomach, and kidneys, hence the necessity of a preparation which is fresh and suitable to the particular subject.

The hypodermic treatment above spoken of is usually continued about one week, when the atropine can generally be dispensed with, but the other two remedies should be continued a week or ten days longer before any further change is made, except as occasion demands. At this time I generally drop one dose of the strychnine and substitute for it the chloride of gold and sodium, beginning with about  $\frac{1}{10}$  grain and gradually increasing to  $\frac{1}{10}$  grain hypodermically. I also add gold to the tonic at about the same time, in suitable doses; but as the patient is taking tonic every two hours while awake, or about eight doses per day, one must be careful and not overdose with the gold, for by so doing he will produce irritation of the stomach, bowels, and bladder, a condition which must be avoided in these cases, if possible.

The chloride of gold and sodium I consider a very useful adjuvant in this treatment, especially in venereal patients; also in patients with a constitutional or hereditary predisposition, as well as in those who have drunk constantly for years. I know that the profession at large have but little faith in the preparations of gold; but having used them for several years,—constantly for over two years,—I am satisfied as to the benefit to be derived from them, especially in the class of patients here mentioned. I have also used the gold preparations in various other diseases with success, which I may report later. In the preparation of remedies to be given hypodermically, care must be taken, lest they prove irritating and result in a sore arm that will be annoying to the physician and a hindrance to the patient.

I also generally give a good physic early in the treatment, as the atropine frequently causes a dryness of the intestinal tract at first, which, if not overcome by an active cathartic, results in the bowels becoming blocked and plugged, thereby hindering treatment. Our patient during this time is given all the whiskey he wants and as long as he wants, provided he can be trusted or has friends who will take care of him and see that nothing out of the ordinary befalls. But just here let me add that the time that the patient will drink the whiskey is usually short, ranging from three to ten days. I generally give for a resting powder at night, or for any headache that may arise, a powder composed of phenacetin and salol, in doses to suit the case, varying from 5 to 15 grains of each, repeated as often as necessary. Should the patient have delirium tremens to begin with, or should delirium develop, I hardly ever begin the treatment at once, but prefer to wait until the activity of the delirium has somewhat subsided,

and give, instead of the regular treatment, hyoscine hydrobromate hypodermically in doses to procure sleep, or should the hyoscine fail, as it does sometimes, I use the valuable remedy chloral hydrate, usually in large doses. The amount can generally be determined after one or two doses have been given. I hardly ever use any of the opiates, as I do not like their action either before, during, or after the regular treatment. The balance of the treatment during the delirium should be supporting, consisting of beef-tea and extracts, celery, cocoa, etc., also whiskey. I have treated patients with and without whiskey, and am fully satisfied that its moderate use is beneficial in the delirium of these cases. The circulatory system, and especially the heart's action, should never be lost sight of during the delirium. If at any time the pulse should become weak and irregular or thready, use hypodermically digitalis, spiritus ammonii aromatici, or nitro-glycerin. Do not wait for the medicine to act through the stomach, for time is a great factor in these cases, and by assisting the circulation and heart's action a person may be saved to life and usefulness. I am much in favor of the aromatic spirits of ammonia, and many times use it in cases in which I have reason to expect delirium, or where it is already developed, and have learned by experience that it is one of the safest remedies; but as its peculiar action in sobering is well known to most physicians, I need not mention it further in this connection.

It is probably well to add here a word of caution in regard to the use of needles in patients with a venereal history or in those of a strumous diathesis. In such cases always sterilize your needle before using on other patients, or, better still, have a separate needle for such patients. One must treat alcoholism as a disease, and must use as much caution and judgment in the management of the case at hand as would be expected or required in the treatment of any other case. Such being the fact, how can one prepare remedies on the wholesale plan, and trust them to physicians who know nothing of the constituents of said remedies, without being guilty of gross negligence? Such a plan is neither practical nor scientific. I believe that a majority of the cases of alcoholism can be cured by the treatment above given, if conducted carefully and each individual case be studied thoroughly from beginning to end by a competent physician.

I would advise any one suffering from alcoholism, and desiring to be cured, to place himself under the care and attention of one who knows what he is giving, what to expect from

his treatment, and how to avoid any bad symptoms from overdosage. If all cases of alcoholism can be treated out of the same bottle, and the same dose given each patient, without any special study of that patient's condition, or without any regard to the number of years the patient has drunk, or the amount he has drunk, and regardless of the injury done such patient, then alcoholism is a habit rather than a disease, and does not require the need of a physician, for the faith cure would work equally well. The length of time required for treatment depends upon the condition of the patient just as much in alcoholism as in any other diseased condition or disease. How can one treat a number of chronic diseases in a certain stipulated time and cure them all? It is a well-known fact that he cannot do it.

The hypodermic part of this treatment should continue for from three to six weeks in ordinary cases, and if your patient can be kept in sight for several weeks longer, so much the better. The patient, on quitting the regular treatment, should be supplied with tonic or medicine sufficient for two or three weeks. This tonic will keep the system in a normal condition, and make it that much easier for him to resist the alcohol. The patient's associates, mode of life, work, exercise, etc., should all be looked after, and he should be advised as much in regard to them as to his medicine.

#### FERRATIN.

BANHOLZER, of Professor Eichhorst's clinic, relates (*Centralbl. f. Inn. Med.*, January 27, 1894) his clinical investigations with this preparation introduced by Schmiedeberg (*Epitome*, December 2, 1893, par. 461). In the cases in question the amount of hæmoglobin in most instances and the number of red cells were estimated. In anæmia following acute disease, the hæmoglobin was quickly increased (over five per cent. in eight days), as also the number of red cells. In chlorosis the same results were visible even in a more marked degree. The general condition was improved and the increase in weight in most cases considerable. The good effects on the appetite were obvious. When compared with Bland's pills, which also give good results, ferratin was found to lead to a greater increase in the hæmoglobin. The results of these investigations are set forth in tabular form. The author concludes that ferratin is a prompt, useful, and harmless remedy in chlorosis and anæmia following past disease, and is well deserving of further trial.—*British Medical Journal*, February 17, 1894.

Foreign subscriptions may be ordered through our agent in England, Mr. H. K. Lewis, Medical Publisher and Bookseller, 136 Gower Street, London. Price 20s. Remittances may be made either by Postal Order or Stamps.

Price to Foreign Subscribers direct (postage included), \$2.50 (20 shillings). English postage-stamps received on remittances.

Editorial communications should be addressed 222 South Fifteenth Street, Philadelphia. Articles intended for the Original Department of the GAZETTE will be accepted only with the understanding that they are contributed to it exclusively.

Authors will receive reprints in pamphlet form, without charge, provided the request for them be written on the articles sent.

Business communications should be addressed to the Publishers.

## Leading Articles.

### PERMANGANATE OF POTASSIUM FOR MORPHINE-POISONING.

IN the last number of the THERAPEUTIC GAZETTE we called attention to the experiments made by Moor, of New York, as to the antidotal power of permanganate of potassium in poisoning by morphine or any of its salts. Since then various contributors to different journals have pointed out a fact of which we were well aware at the time our leading article was written,—namely, that experiments upon the lower animals with morphine were valueless, so far as antidotes were concerned, unless the doses of morphine given were exceedingly large, it being a well-known fact to all who have worked in a physiological laboratory that dogs in particular require enormous doses—many grains of morphine—to seriously affect them. There is, therefore,

this possibility of fallacy underlying the experiments of Dr. Moor. On the other hand, it is to be remembered that the human being is far more susceptible to morphine, and that Moor took himself sufficiently large doses to produce death in the ordinary individual unless an antidote followed the ingestion of the drug. The possible fallacy in this respect might be that the human being who took morphine was able to bear large doses of it because he had accustomed his system to the drug, either by habit or through necessity. Attention is called to these facts by Dr. Andrews, of Montgomery, Ala., in the *Medical Record* of March 10, in which he showed that if only 4 to 6 grains of morphine were given to a dog, recovery nearly always took place, even if no antidote was given, a fact already well known. While these criticisms tend to throw discredit upon the employment of permanganate of potassium for this purpose, it should be remembered, on the other hand, that chemists have known for years that the vegetable alkaloids were readily decomposed by powerful oxidizing agents, and we have ourselves repeatedly produced disorganization of morphine and similar substances by the addition of permanganate of potassium to this solution in a test-tube. It is also interesting to note that in the Philadelphia College of Pharmacy permanganate of potassium has been taught to be an antidote of power in all forms of alkaloidal poisoning, more particularly that of morphine. The profession, therefore, still stands ready to accept as of value or throw aside as valueless the studies to which we have called attention, and appreciates the fact that permanganate only acts as an antidote when it can attack the alkaloid in the stomach, and not after it is absorbed. Under the latter circumstances the physiological antidotes—strong black coffee and strychnine—are to be used.

### THE TREATMENT OF HEADACHES WHICH FAIL TO YIELD TO COAL-TAR PRODUCTS.

TEN years ago, before the large number of pain-relieving drugs of the coal-tar group had been introduced into medicine, opium and Indian hemp were our most reliable drugs for the relief of pain in the head. While cannabis indica suffered temporary disuse through the very wide employment of antipyrin and its relatives, there is no doubt that there still remain a number of cases which are benefited by it and in which the coal-tar products fail. Indeed, it is

doubtful whether these substances are ever as efficacious in the treatment of true migraine or megrim as is cannabis indica, particularly if at the time of the attack the cannabis indica is combined with full doses of gelsemium. Under these circumstances the best results seem to follow the administration of tincture of cannabis indica in the dose of 5 drops three times a day during the intervals between the attacks, and at the time of the attack to administer from 20 to 30 drops of the tincture, or 5 to 20 drops of the fluid extract of hemp, with 10 to 20 drops of the tincture of gelsemium as soon as the first dimming of vision or other prodromal sign of the attack manifests itself. Naturally, so full a dose of a good preparation of gelsemium very markedly reduces the pulse-force, and many patients who take these doses are forced to lie quiet on their backs in bed or on a sofa until the struggle between the drug and the attack of migraine is over. It is true that much disappointment has existed when cannabis indica has been administered, and that many of the profession have cast it aside, being unable to obtain a pharmaceutical preparation of it which would be therapeutically active. We have used the preparation made by Parke, Davis & Co. for nearly ten years with constantly good results.

A word of caution in regard to the employment of the tincture of gelsemium is also necessary. In those cases which already have a feeble circulation the full doses named are contraindicated, and we understand that in some of the southwestern portions of the United States a concentrated tincture of gelsemium is frequently dispensed, the dose of which is 1 or 2 minims at the most. Of course we refer in this article to the tincture of gelsemium which is official in the United States Pharmacopœia.

---

*THE USE OF PERMANGANATE OF POTASSIUM AND BINOXIDE OF MANGANESE IN THE TREATMENT OF AMENORRHOEA.*

---

PRACTITIONERS of experience always recognize the necessity of treating the amenorrhœa of anæmic women with iron and other drugs which are supposed to increase the richness of the blood, and in many instances they address their efforts not only to the condition of the blood itself, but to the atonic state of the general system and of the generative organs which results in this disordered function. Under these circumstances, out-door life, nu-

tritious food, the avoidance of late hours and of excessive fatigue are all to be strongly urged upon the patient, and in most instances the efforts of the physician are successful, producing a normal catamenial flow.

There is another class of patients, however, who suffer from amenorrhœa which is apparently not dependent upon anæmia or upon general systemic atony. Indeed, in many instances it seems almost impossible to determine the cause of the difficulty. In these instances we have found the permanganate of potassium or the binoxide of manganese in the dose of 2 grains three times a day, in pill, a valuable method of treatment. Either drug should be given for about one week before the expected period, and continued during that time. In persons who have an exceedingly irritable gastric mucous membrane this treatment sometimes results in some distress in the stomach or evidences of slight indigestion, but, as a rule, it is well borne by the patient.

---

*SOME FURTHER FACTS CONCERNING THE ALKALOIDS OF HYOSCYAMUS.*

---

IN the March number of the THERAPEUTIC GAZETTE we published a leading article upon the subject of "The Untoward Effects of Hyoscine in Acute Alcoholism," and our attention has once more been called to this question by an interesting paper by Spratling, of New York, published in the *Medical Record*, in which he reports the results of his clinical investigations as to the action of hyoscyamine and hyoscine, both upon patients in the asylums with which he has been connected and upon his own person. After quoting several statements from contemporary authors as to the dangerous effects which may be produced by these alkaloids of hyoscyamus, he asserts that, in his opinion, many cases, while temporarily quieted and benefited by these drugs, are permanently injured by their use. He thinks that diffuse headache which has persisted is one of the unpleasant after-effects, and that the disturbances of vision, dryness of the mouth, and the failure of secretion of the glands in the alimentary canal are additional reasons for the non-employment of the remedy. He admits that the drug is of value in cases of paralysis agitans, and that some cases of mania which are very excessive and resistant to other drugs may yield under the influence of one of these two alkaloids, provided that the dose is small. Indeed, he thinks that in many of these cases the good results follow the mental effect of the

hypodermic needle rather than by any direct influence of the drug. He concludes, finally, that hyoscyamine should never be given in doses of any size in disorders of the mind; that it should never be given in any disease in which there is the least degree of inflammatory action or congestion going on, particularly in the brain and its membranes; that it should never be given to a patient who is in a condition of exhaustion, or who is prone to pass into such a condition; that it should not be given in any case for the purpose of producing sleep. He also makes the somewhat unguarded assertion that there is no good authority for believing that it acts as an hypnotic. Finally, he thinks it only of value in chronic conditions of the nervous system manifesting tremor and other mild motor disturbances. We think that Dr. Spratling's paper is of value because it emphasizes the fact, which we have already stated elsewhere, that hyoscyamine and hyoscine, so far as their action upon the general system is concerned, have a very limited sphere of usefulness. In certain cases, such as those which have just been pointed out, they undeniably do good, and we would add nocturnal emissions to the list of conditions which are benefited by the use of hyoscine. Associated with the hyoscine in the treatment of this condition should be instituted, of course, tonic measures and baths. These alkaloids, while they will continue to be employed for the few conditions named, have not fulfilled the expectations which it was hoped they would fulfil some years ago.

#### THE THERAPEUTIC VALUE OF SARSAPARILLA.

IN the *Medical Record* for February 17, 1894, is a short editorial article upon the value of sarsaparilla, and the conclusion which is reached is that it is practically a useless substance, which should be dropped from the Pharmacopœias of the future, and that its use is based more on theory and custom than on any evidence that it does good in disease. We think its value in covering the taste of iodide of potassium is ample reason for its continuing to be a recognized substance in the Pharmacopœia; but aside from this, and aside from the fact that distinct therapeutic properties cannot be assigned to it, there is, nevertheless, a widespread belief on the part of many members of the profession that the addition of sarsaparilla to iodide of potassium in some way distinctly increases the medicinal value of the iodine compound. No less an authority than Wood

asserts that in some cases of syphilis iodide of potassium fails when given alone, and succeeds in some way which we cannot understand if prescribed with sarsaparilla. Whether the sarsaparilla aids in any way in maintaining the activity of absorption in the stomach, or whether it possesses feeble curative powers in itself, no one, so far as we know, attempts to determine, but we are confident that the views enunciated by the author already quoted are correct.

#### THE TREATMENT OF MEMBRANOUS AND DIPHThERITIC CONJUNCTIVITIS.

ALTHOUGH croupous inflammation and superficial diphtheritis of the conjunctiva are closely related, and although many modern writers are disinclined to maintain a distinction between these two affections, there can be little doubt that a sufficient number of each class, well marked, render the maintenance of a differentiation scientifically worthy. Croupous conjunctivitis in its pure type is uncommon and its etiology uncertain. It differs from the diphtheritic type chiefly in the fact that there is a painless swelling of the lids and a membranous exudation upon the surface of the conjunctiva, while the latter is characterized by a board-like induration of the palpebræ and an exudation within the layers of the conjunctiva which leads to death of the invaded tissues, and by pressure tends to destroy the nutrition of the cornea. One therapeutic rule, however, is applicable to both affections,—namely, that nitrate of silver, the standard application in severe catarrhal and purulent conjunctivitis, is contraindicated.

In a recent article by Valude (*Annales d'Oculistique*, February, 1894), concerning the various types of conjunctivitis associated with false membrane, this point receives especial attention. He insists that three methods of treatment, often recommended, should receive only condemnation, whether we deal with a pseudo-membranous or a true diphtheritic conjunctivitis,—namely, nitrate of silver, iced compresses, and sublimate lotion. Nitrate of silver has often been shown to be detrimental under these circumstances, cold compresses are likely to add to the depression which the cornea already feels, while sublimate can do no special good, so far as the bactericidal influence is concerned, and is, as is well known, capable of injuring the corneal epithelium.

In Valude's experience, the essential basis of the treatment consists of sprays, frequently used. These should always be warmed, and may be

composed of boric acid or any non-irritant, mildly antiseptic liquid. He prefers the following lotion :

Extract of opium, gr. iss;  
Sterilized water, Oii;

which may easily be prepared by dropping into two pints of warm boiled water ten drops of a standard solution, composed of sterilized water and glycerin, each half a drachm, and extract of opium, fifteen grains. After experimenting with different antiseptic lotions in a large service, he has adopted this liquid, which has proved to be of the greatest advantage in soothing pain and diminishing secretion. Considerable swelling of the lids may be managed by using, instead of the lotion just described, a naphtholated solution; but, as he points out, this swelling is not so frequent as in true purulent ophthalmia. In addition to irrigations with the antiseptic liquid, he advises an iodoform salve (1 to 50), to be applied twice a day to the conjunctival cul-de-sac, especially if ulcers of the cornea exist. If there is much suppuration, terpinol is recommended. Terpinol, mixed with equal parts of oil of vaseline or oil of sweet almonds, takes the place of the excipient in the iodoform salve.

Referring to the well-known recommendation of Fieuzal, to touch the false membrane in these cases with lemon-juice, Valude states that he has seen improvement occur, but is inclined to attribute it to careful irrigation rather than to any specific action of the medicament. If it is applied at all, it should be done carefully, with a camel's-hair brush dipped in a solution of the juice, by touching only the false, adhering membrane.

In connection with Valude's experiences in membranous and diphtheritic conjunctivitis, it is interesting to refer to the researches of Gilbert Surdille, elsewhere abstracted in full. He thinks that Fieuzal has rendered a real service in reviving the old remedy,—lemon-juice,—and recommends it, provided too much confidence is not placed in its virtues. Believing the affection to be a microbic disease, he is inclined to employ phenic acid in a formula composed of five drachms of glycerin and half a drachm of phenic acid. He proceeds as follows: The eyelids are reversed and the conjunctiva washed with a jet of biniodide of mercury (1 to 20,000). The false membrane is then removed with an alkaline solution, borax or baborate of sodium, after which, with a wad of cotton dipped in the carbolic-acid and glycerin solution, all the diseased areas are thoroughly anointed. In the interval he applies a salve of

methyl-blue (1 to 1000), because Janicke has demonstrated that Loeffler's bacillus does not grow in bouillon containing methyl-blue, even in very minute proportions.

Surdille very properly discards bloodletting, and also, but this, we think, without good reason, the administration of mercury. In our own experience,—somewhat limited, owing to the infrequency of the affection in this country,—in addition to copious irrigation with warm antiseptic solutions and the instillation of atropine, the best results followed the internal administration of quinine, iron, and mercury, the quinine in suppositories, the iron as the tincture, and the mercury either as calomel or bichloride. The last remedy, following Jacobi's recommendation, may be exhibited in milk or water hourly in the dose of  $\frac{1}{16}$  to  $\frac{1}{8}$  grain to children from three to six years of age. Even if the specific action of the remedy is doubted, it has an alterative and tonic influence under these circumstances which is not to be despised. To sum up: During epidemics of diphtheria, especially when the nasal mucous membrane is also affected, the conjunctiva may become inoculated, and a form of conjunctivitis develop almost certain to destroy sight unless prompt treatment is applied. This treatment should consist of copious irrigations with a warmed, mild antiseptic fluid. Boric acid fulfils the indications, and we are inclined to agree with Valude that bichloride has no advantages, and is capable of introducing distinct disadvantages. Atropine drops are indicated if there is corneal ulceration, or atropine may be used at night and eserine during the day, in the manner already several times described in these columns in connection with the ulceration occurring in ophthalmia neonatorum. Iodoform salve should be freely applied within the conjunctival cul-de-sac; indeed, vaseline itself is efficient under these circumstances. Finally, all cauterant applications, particularly nitrate of silver, should be avoided. Very hot water conserves the nutrition of the cornea, and is preferable to the cold applications which are so effectual in the early stages of a purulent ophthalmia. With the special remedies recommended by Valude and Surdille we have no experience, but they suggest trial. Lemon-juice should not be forgotten, and there is enough evidence that good has followed its use to place it among the medicaments best suited to the treatment of this affection. In spite of high authority, we have no confidence in the application of quinine or flowers of sulphur to the diseased lids.

*PRURITUS VULVÆ.*

THE persistent tickling, itching, and burning of pruritus vulvæ points not only to simple hyperæmic irritation, but to a more marked involvement of the skin-covering and its terminal nerve-bulb filament. Webster, on the basis of microscopic examination of excised portions of skin affected with pruritus, describes a subacute inflammation of the papillary bodies and advanced fibrosis of the nerve-endings, especially marked in the region of the clitoris and the upper portion of the smaller labia. These observations strongly suggest that the disease is in reality an inflammatory neurosis of the vulvar corium.

The severe forms are always associated with local lesion. Even though this is not perceptible to the casual examination, microscopic research will reveal thickening and infiltration.

The pruritus is usually caused by a local disease of the vulva. This region is swarming in germs. It is claimed that in diabetic pruritus the leptothrix and allied organisms occasion the deep skin inflammation, but others of the mycoses, such as that due to the *oidium albicans*, are often attended with itching.

Webster classifies the cases of pruritus as follows: 1. Endogenous cases. Under this heading are included those in which the blood is altered, as from icterus, chronic nephritis, diabetes mellitus, the waste products circulating in the blood acting upon the terminal nerve-filaments and occasioning itching. Under the same heading would be included the pruritus due to medicines, such as morphine, iodoform, alcohol, etc. Under the endogenous cases would also be classified pruritus caused by varices or congestion of the pudendal veins of the hemorrhoids or of the pampiniform plexus, such as may come from a weak heart, pregnancy, hemorrhoids, or displacement or overgrowths of the womb. Moreover, certain well-known skin-diseases may occasion vulvar itching. Thus, erythema, herpes, urticaria, and certain forms of eczema may after an acute attack leave permanent alterations of the papillary bodies, which react upon the nerve-endings. Finally, fermentation in the intestinal tract may give rise to products which, absorbed into the blood, may act upon the nerve-endings. The frequent occurrence of constipation in women makes this a causative factor of no little importance.

Under the exogenous cases are classed those due to alteration or increased secretions of the vulvar glands, hyperidrosis, seborrhœa, polyuria with either altered or normal urine, dis-

eased secretion from the vulva, vagina, and uterus, catarrh and suppurative secretions from the rectum, especially discharges from inflamed piles. These secretions are irritative partly from their direct chemical action, partly from their decomposition, irritant products being formed which act directly upon the macerated epithelium, causing erythema, intertrigo, eczema, and in certain cases prurogenous vulvitis. Causes of a parasitic nature are also frequently operative in causing pruritus. Thus, the pediculi, the ascarides, the oxyuris vermicularis, leptothrix, *oidium albicans*, *micrococcus urænae*, *gonococcus*, *smegma bacillus*, the ordinary putrefactive bacteria, and the streptococci and staphylococci are said to be, if not the primary and predisposing, at least the secondary exciting causes of itching.

Of mechanical causes, masturbation will perhaps take the first rank; persistent washing and friction, especially when applied by means of sponges which are always unclean, encourages infection. The symptoms are aggravated by the scratching and rubbing occasioned by the symptom. Thermic influences are also operative; thus, there is a winter and summer pruritus.

Usually careful examination as to etiology indicates the most promising method of cure. Thus, where the disease is due to parasites, lack of cleanliness, to drugs, to decomposing discharges, to venous congestion, etc., the efficient treatment is obviously removal of the cause of the diseased local conditions. In those cases dependent upon visceral alteration, the local treatment must be subordinate to attention to the general condition. Thus, the appropriate regimen must be indicated in each instance in accordance with whether the patient be diabetic, jaundiced, subject to Bright's disease, or suffering from venous congestion incident to heart weakness. The gouty or rheumatic diathesis must be properly treated.

Antiseptics as local applications are most useful. These are generally combined with astringents and with local anesthetics.

Among the favorite methods of treatment are prolonged hot baths, followed by hot douches. These douches should be antiseptic and anæsthetic; thus, solutions of carbolic acid as hot as can be borne are of special service. It is noteworthy that the area affected by pruritus can stand a much stronger solution than can be used upon a healthy surface; thus, irrigations of 1 to 40 or 1 to 20 may be made. Bichloride is also serviceable, but the anæsthetic effect of the carbolic acid is lacking in this drug. A favorite prescription of D. Hayes Agnew, ~~was~~

ommended as almost a specific in pruritus ani, is:

R Sulphate of zinc,  
Alum, of each, equal parts.

To be mixed and heated until the water of crystallization is driven off. A drachm of this is added to an ounce of water and is applied locally. At times the carbolic lotion proves too irritating; then a simple astringent may be employed, such as fluid extract of hydrastis, 1 drachm to 1 pint, or hamamelis, fifty per cent., or even full strength. After prolonged douching, either with hot solutions of hydrastis or hamamelis, the parts may be bathed with a prescription made up of,—

R Menthol, gr. i;  
Cocaine, gr. xxxvi;  
Alcohol,  
Water, of each, ʒi.

Or an ointment may be applied made up of,—

R Menthol, ʒi;  
Simple cerate, ʒii;  
Oil of sweet almonds, ʒi;  
Carbolic acid, ʒi;  
Pulv. zinc oxide, ʒii.

Or,

R Menthol, ʒi;  
Carbolic acid, ʒi;  
Lanolin, ʒii;  
Pulv. zinc oxide, ʒii;  
Unguent. zinc oxide, ʒi.

Or a strong lotion of carbolic acid may be dabbed on, according to the following formula:

R Carbolic acid, ʒii;  
Glycerin,  
Water, of each, ʒix.

Painting the vulva with glycerin mixed with a ten-per-cent. solution of chloroform and glycerin, with a ten-per-cent. solution of carbolic acid and glycerin and alcohol, or a solution of nitrate of silver of similar strength, is sometimes serviceable.

Madden recommends oleate of chloral painted over the parts. This is a compound formed of equal parts of camphor, chloral, and oleic acid. Where the disease is due to irritating uterine or vaginal discharges, he recommends the introduction of a tampon of cotton-wool loaded with equal parts of finely-powdered alum and sugar, and carried within the vulvar orifice. He holds that in his dispensary practice black wash is regarded as a most generally useful as well as a very cheap available application in such cases.

Goodell recommends a strong emulsion of iodoform and glycerin (ten to twenty per cent.).

Skene commends vaginal douches of acetate of lead, and dusts subnitrate of bismuth on the labiæ to prevent friction. This he holds is especially serviceable in diabetic cases. In the cases in which the etiology was obscure, he states that the remedies which have given him the best results are bichloride of mercury in emulsion of bitter almonds, one grain to the ounce, applied to the parts affected twice a day; a powder composed of one grain of morphine to two grains of chalk, applied night and morning; equal parts of tincture of opium, iodine, and aconite, and eight per cent. of carbolic acid, applied once a day; and ethereal solution of iodoform, applied by means of an atomizer. In some cases application of equal parts of carbolic acid and tincture of iodine relieved permanently. This was used in one case by means of an atomizer, the spray being driven under high air-pressure. An acute inflammation followed, but after the patient recovered from this the pruritus did not return. In certain cases, in spite of every local and general treatment, disease persists and renders life almost unendurable. Under such circumstances there remains surgical intervention.

Carrard reported the first case of surgical intervention. The clitoris was the part affected; its removal was followed by cure.

Schroeder carefully localized the points of itching, and then removed them by section in five cases. In one of these cases the disease was complicated by carcinoma. In another, in addition to excision of the diseased vulvar surface, a ring of skin was taken from around the anus. In the three remaining cases the disease was purely pruritus vulvæ. In the first, a small area was removed from the right labium majus; in the second, the right labium majus was excised, and following this several lesser operations were performed; in the third, in which both the clitoris and lower lips were involved, the operation was more extensive. The women all recovered. The operator stated that intervention should only be attempted when the itching was localized, and cautions against attempting to cure a widely diffused pruritus by the knife.

Küstner also reports three successful cases.

Martin reports four, and a number of other operators state that the results were successful.

Sänger (*Centralblatt für Gynäkologie*, No. 7, 1894) contributes the full notes of two cases, both entirely successful.

He closes his thesis with the following statement :

The partial or total extirpation of the vulva is an entirely legitimate operation in cases of chronic pruriginous vulvitis not curable by other means. In younger persons the surgeon should be content with partial operation. In aged persons, when the disease is widely extended, the whole vulva, including the glans clitoris, should be entirely extirpated and the wound closed by plastic operation.

### OSTEOMALACIA TREATED BY CHLOROFORM INHALATIONS.

The correspondent of the *Medical Press and Circular*, writing from Vienna under date of January 26, gives an account of a patient presented by Latzka at one of the medical meetings in that city. The patient had quite recovered, it was stated, from osteomalacia after chloroform narcosis. Latzka pointed out that at the present time there were two theories enunciated by Petroni that might be cited as the proximate origin of the disease,—viz., the micro-organism or nitrification theory, and the effect of castration and Porro's operation, which properly depend upon chloroform narcosis. Latzka said that he had observed a marked change in osteomalacia for a few weeks after the application of chloroform, which frequently proved to be temporary. This led him to question the theories more accurately, and in his investigations, according to the proofs of Petroni, who maintained that nitrates were constantly in the urine of the osteomalacia, he failed to satisfy himself that any constant relation existed between the nitrites and the disease. Indeed, three out of seven cases carefully followed failed entirely in this particular; two of the same number presented an occasional testimony after the urine had stood for some time, the remainder very rarely. In the fresh urine, nitrites could never positively be proved present. In this, he pointed out, he was not alone, as Karplus had obtained similar results. He considered the nitrification hypothesis of Petroni to be unsupported from the present proofs.

With regard to the second hypothesis, he brought forward the history of ten cases which had fallen under his own observations; one of these was a male; six were puerperal osteomalacia; the other three were non-puerperal. In these ten cases his treatment was simply anæ-

thesia by chloroform, and of the ten only one remained unaffected, two others were but slightly improved, while the remaining seven were decidedly much better, but, unhappily, the recovery was of a temporary character. Only one of these cases which he showed had retained any lasting effect. This case had been treated with chloroform seven months ago; the subjective and objective pains had all disappeared, the former elastic pelvis is now solid, and the patient considers herself at present perfectly well.

A second of this number is greatly improved, which possesses some interest from the former treatment under Schauta, who had operated four months previously for double-sided salpingitis with ether, but without any influence on the osteomalacia or relief to the patient. Immediately after the chloroform narcosis, four months later, the pain was relieved, the luxated joints became firmer, and the patient soon became so much restored that she could move about. As stated above, these brilliant results were but temporary. On this account he attributes many of the successes in castration and Porro's operation to the chloroform and not to the operation itself, although he admits that these operations have cut off the function of generation and prevented the return of the disease. In this manner he reasons on the cause of return of many successfully treated cases of osteomalacia with phosphorus, wherein the first pregnancy excites the disease. In the chloroform treatment he considers the disease checked, but on recommencement of the menses the disease is excited. From the results obtained he is inclined to believe that some modification of chloroform narcosis may be successfully pursued in the treatment of osteomalacia.

### INTERSTITIAL INJECTIONS OF IODINE IN THE TREATMENT OF GOITRE.

DR. GEORGES MANGIN, an interne of the Paris hospitals, contributes an article on this subject to the *Gazette Médicale de Paris* for January 13, in which he gives the details of the procedure as practised by Dr. Duguet. These injections, he says, may be employed in any case of goitre, but they are especially appropriate in those of medium size, of comparatively recent formation, fleshy, not much indurated, and not yet calcified, whether they are cystic or not. This little operation succeeds best in hydatid cysts of the thyroid body, which are always cured by a single injection. Contraindications are: albumin or sugar in the urine, the existence of the menstrual flow, ex-

ophthalmic goitre, cancerous goitre, and a cystic goitre containing blood (only a relative contraindication). Accidents in this treatment have occurred to certain operators only because they have not strictly followed the letter of M. Duguet's instructions. Before undertaking the operation certain precautions should be taken. The patient's urine should be examined; it should be ascertained if she is menstruating; and the neck should be measured immediately above the goitre, around it, and below it, and this measurement should be repeated before each injection. Various liquids have been tried, but none is so good as pure tincture of iodine. The needle of the syringe should be of steel or of irido-platinum, and it should be very sharp. After being used it should be cleansed in a very weak solution of ammonium chloride or potassium iodide, and then left until it is to be used again in a ten-per-cent. oily solution of carbolic acid. This having been done, it is necessary to determine the most appropriate point for inserting the needle. The operator should assure himself that the tumor has no souffle and that it presents no expansile movements; then he should palpate it carefully to find the central, fleshy, least resistant part, as far as possible from the large veins which sometimes ramify over its surface and also from any arterial pulsations. Into that point he should plunge the needle. The syringe is to be filled with tincture of iodine and the air expelled. Then the operator raises the patient's head in such a way as to make the throat prominent, holds the tumor immovable between the thumb and forefinger of the left hand, compressing it gently, with the right hand plunges the needle slowly to the depth of from half an inch to an inch, and waits to see if any liquid escapes through it. If pure blood flows, the procedure is to be stopped, the needle is to be withdrawn, and an attempt made to introduce it in one or two other situations, until one is found from which there is no flow of blood. If this cannot be done, the idea of administering the injection must be given up for the time being. If a coffee-colored liquid flows, the syringe should be connected with the needle, and, if the cyst is small, the liquid aspirated, and then the injection proceeded with. If, on the contrary, the cyst is large, slow aspiration should be performed with a regular aspirator. In case the injection is to be proceeded with, the syringe filled with tincture of iodine is to be connected with a needle and the piston pushed down very gently and slowly, while the operator observes the patient's face and interrogates him as to his sensations. At the first injection

not more than half or three-quarters of a syringe-ful should be injected. When the injection has been made, the needle, still connected with the syringe, is to be withdrawn rather suddenly; then the left forefinger is to be placed over the puncture in order to stop the slight discharge which might occur. If the patient's neck or the operator's hands have been soiled by the tincture of iodine, they should be washed in ammonia-water. Usually nothing special occurs as the immediate result of these injections, but sometimes there is observed local heat, with tumefaction, a little embarrassment of the movements of the neck and in swallowing, and occasionally some painful sensations about the jaw, the teeth, or the ear of the side on which the injection has been made. These are benign phenomena and do not last more than a day or two. They constitute no reason for not repeating the injection weekly, as should be done. Occasionally there is feverishness, with chills, headache, depression, agitation, sleeplessness, and gastric disturbance, symptomatic of a slight degree of acute iodism, which usually does not last more than from a few hours to a day or two. The author closes with the statements that this method of treatment acts by causing absorption and a non-suppurative inflammation, and that it is absolutely harmless and of marvellous efficacy when it is employed early and with discernment.—*New York Medical Journal*, February 10, 1894.

#### TREATMENT OF TUBERCULOSIS WITH CINNAMIC ACID.

PROFESSOR ALBERT LANDERER, of Leipsic (*Therapeutische Monatshefte*, February, 1894) highly recommends intravenous injections of cinnamic acid in the treatment of tuberculosis. Cinnamic acid and its salts are strongly chemotactic. Intravenous injections call forth a marked leucocytosis. The polynuclear leucocytes are increased, and, to a less degree, the eosinophiles. Leucocytosis begins in one and a half or two hours after injection, and reaches its maximum in eight hours, with an increase of two and a half times in the number of leucocytes, which seem to come especially from the spleen. Leucocytosis is not nearly so decided after intramuscular or subcutaneous injections. The number of red blood-cells, even when injections are long continued, is not lessened, and the same is true of hæmoglobin.

Landerer reports:

1. A series of thirty-three cases of chronic

lung-tuberculosis without demonstrable cavities. Of these, all but two were cured.

2. A series of twenty-two cases with cavities, but without marked fever. Only two are known to have died, nothing definite is known of six, and it is admitted that others may have died.

3. A series of eight cases presenting continuous high fever. These cases are hopeless (six of the eight died), but most of the patients feel better and probably live longer.

4. A series of fifteen cases of galloping consumption; eight of the patients died and four more will probably die; two cases have remained cured for two years and one for three months.

Landerer saw also two cases of tuberculosis of the intestine, one case of tabes mesenterica, and two of mediastinal tubercular tumor. These were cured. A case of genito-urinary tuberculosis was considerably improved.

For the technical details of this treatment, Landerer refers his readers to his book, "Amweisung zur Behandlung der Tuberculose mit Zimmtsäure," Leipsic, F. C. W. Vogel. To statements there made he adds now that in many cases the emulsion may be replaced by a five-per-cent. watery solution of cinnaminate of sodium, the dose to be injected remaining about the same or somewhat larger; the injection may be given three times a week. For advanced cases, at least at first, only the watery solution can be used. Even if the intravenous injection is not difficult, it should be carefully practised, and a careful asepsis also belongs to it.

In surgical tuberculosis, instead of the emulsion, cinnaminate of sodium (five per cent.) and (especially to inject in the joint cavities) a suspension of cinnamic acid in glycerin (1 to 20 to 1 to 10) may be used. Both preparations must be immersed in a water-bath for at least ten minutes to sterilize them, and may be kept in tightly-closed bottles for weeks.

Sometimes a rise in temperature is noted when the first injection is made.

Injections are made in the fungous mass, in the joint cavities, and in the gluteal muscles, where the injections of mercurial salts are given.

#### THE SUBCUTANEOUS INFUSION OF COMMON SALT FOR ACUTE ANÆMIA.

DR. O. FEIS (*Therapeutische Monatshefte*, February, 1894) reports three cases of extreme anæmia after abdominal surgical operations, in which the injection of common salt was apparently the means of saving life.

The instruments for subcutaneous infusion

are perfectly simple. All that is needed is a tolerably strong canula, a rubber tube, and a funnel.

The infraclavicular region is the best place to make the injection; the skin and all instruments are disinfected in the usual way, the skin raised in folds, and the needle, with the salt solution flowing (to prevent the introduction of air) inserted. From a moderate height the fluid is let flow, the funnel being kept full. If too much collects under the skin, it is stroked away with a gentle massage.

In from ten to fifteen minutes one quart may be infused in this way. The place of the puncture is finally closed with sterilized cotton batting, fastened with sticking-plaster. Drs. Feis and Schwalm have prepared pastilles of chemically pure salt, which physicians may have always at hand.

#### THE MEDICINAL TREATMENT OF MUCO-MEMBRANOUS ENTERITIS.

From a communication made to the Académie de Médecine by PROFESSOR GERMAIN SÉE, relative to the drug treatment of muco-membranous enteritis, the following abstract is published by *La Médecine Moderne* of January 3, 1894:

"A. *Purgatives*, comprising,—

"1. Flaxseed or *psyllium* (mechanical means).

"2. Senna, combined with a vaso-motor constrictor: *hydrastis canadensis*.

"3. Castor oil.

"4. Olive oil in large doses, internally or by enemata.

"A few words now in regard to each one of these four means of producing evacuation.

"1. *Flaxseed* or *Psyllium*.—The patient, immediately after each one of the three principal meals, should take a tablespoonful of pure flaxseed, placed for three or four minutes in a quarter of a glassful of cold water. If the flaxseed is objectionable to the patient, it can be substituted with *psyllium*. These substances are sufficient in themselves, in the majority of cases, to produce movements of the bowels, without having to resort to the administration of the various mineral-waters, some of which, owing to the sulphate of sodium present in them, often give rise to constipation afterwards. Objection has been made against inert substances as possessing the disadvantage of causing obstruction of the cæcum; but in the many cases that I have observed, in an experience of over twenty years, in which patients have constantly made use of them, I have not met with a single

in which the obstruction could not be easily done away with by a mild laxative.

"2. *Hydrastis Canadensis* and *Senna*.—If the use of inert bodies, like flaxseed, is not sufficiently efficacious to move the bowels, I am in the habit of prescribing a mixture which has great advantages. It can be daily administered at meal-time, without causing too much purgation and without rendering patients unable to attend to their various occupations. It is a combination of senna and *hydrastis canadensis*. Why do I prefer senna to other purgatives, and why do I combine it with *hydrastis canadensis*? Here are my reasons: The leaves of senna, in moderate doses (1 to 2 grammes), cause the expulsion of gases, and, after five or six hours, solid passages, unattended with colicky pains. In doses of from 2 to 4 grammes, the senna leaves exercise all their purgative power without causing congestion of the intestines. The most remarkable fact about this action is that it does not give rise to constipation, the drug exerting an influence particularly on the large intestine. The therapeutic effects of *hydrastis canadensis* are the result of excitation of the vaso-motor centres, accompanied with decided contraction of the vessels and elevation of the blood-pressure. These effects tend to correct the vascular relaxation caused by the senna, and hence the association of both remedies. The pilular form appears to me the best for administration purposes, according to the following formula:

R Alcoholic extract of *hydrastis canadensis*, 30 to 45 grains;

Senna leaves bathed in alcohol,  $\text{ʒiiss}$ .

M. and make 50 pills.

Sig.—1 pill after each meal.

"3. *Castor Oil*.—From time to time it is convenient to suspend the use of the flaxseed and the pills of *hydrastis*, in order to induce a free but not too strong purgation. In these cases no saline purgative, no drastic remedy, can be employed to better advantage than castor oil in doses of from 150 to 375 grains. In the course of one to three hours evacuations are produced without pain and without intestinal irritation. The substance may be employed in inflammatory conditions of the bowels, and for better reasons in muco-membranous irritations of the intestines.

"4. *Olive Oil in Large Doses*.—Since the treatment of hepatic colic by large doses of olive oil has been introduced into France, through the work of American physicians, I have tried the same treatment in mucous enteritis with remarkable and often decided suc-

cess. The oil may be administered, either by itself or in sugared tea, in doses of from 3 to 4 dessertspoonfuls the first day, morning and evening; the second day at noon, the same dose before the second meal; the third day, a glass at the same hours; and the fourth day, a whole glass at once. After this the patient must rest for four or five days,—that is, the medication should be suspended, to be again renewed as prescribed. If the first trial shows a non-tolerance of the drug on the part of the patient, the method must be abandoned. Generally, however, the oil is well borne, more so than may be supposed, and in these cases the muco-fæcal movements produce an unexpected relief and sometimes a cure, at least for a considerable time. The large enemata of olive oil proposed by Pleiner appear to do some good, but this cannot be compared to that effected when the oil is ingested through the mouth.

"B. *Sedatives*.

"The second indication is to assuage pain without resorting to narcotics or mydriatics. Narcotics like morphine and mydriatics like belladonna cause constipation and anorexia, which interfere with nutrition. These substances, therefore, being eliminated, I know of no better medicaments in the management of this second indication than the bromides of calcium and strontium and cannabis. I say the bromides of calcium and strontium. The bromides of sodium and potassium ought not, in fact, to be employed, and for various reasons. They irritate the stomach, weaken the digestive powers, and diminish the general forces of the patient. These disadvantages are not met with in the bromides of calcium and strontium, which are well tolerated by the stomach. From 2 to 3 grammes in the day are sufficient to lessen the sensibility of the mucous membrane of the stomach, especially when 1 gramme in solution is taken *during* each one of the principal meals. The following combination is advised:

R Bromide of calcium,  
Chloride of calcium, of each,  $\text{ʒii}$ ;  
Distilled water, Oi.

"In default of the bromides, he prescribes cannabis indica, as follows:

R Solution of gum-arabic,  $\text{ʒiv}$ ;  
Extract of cannabis indica, gr. ii. M.  
Sig.—3 tablespoonfuls per day, 1 before each meal.

"If great pain is present, one of the best modes of producing relief is the administration of menthol, in the following manner:

R Menthol, gr. ii-iii;  
Alcohol, q. s. to dissolve it;  
Distilled water, Oss. M.

Sig.—Two tablespoonfuls by the mouth t. d.

*“C. Regarding Fermentation.”*

“To diminish fermentation is the third indication to consider. Many popular remedies have been used for this purpose, such as the carminatives like aniseed, antiputrefactives like charcoal, etc., but their value is doubtful and sometimes they exert a noxious influence. Charcoal especially may injure the gastrointestinal mucous membrane. I know of three efficacious means only by which to meet this indication, and I am in the habit of combining them. The first is the administration of the phosphate of sodium, which I place above any other antiputrefactive or absorbent substance. With from 45 to 60 grains of phosphate of sodium a day I have obtained remarkable results. The amount of the drug is divided into three parts, each one of which is ordered to be taken in a little water, after meals.

“For flatulence, the best remedies are salicylic acid in doses of 3 grains and salicylate of sodium associated with 6 grains of the phosphate of sodium. These drugs will at the same time diminish the sensibility of the mucous membrane. Borate of sodium or borax is an excellent substitute for the agents mentioned, and it particularly aids the digestion of milk.

“I will now, by way of parenthesis, refer to the great medicaments favored by a certain school. I allude to the antitoxic and antibacterial remedies. *A priori* it would seem that nothing could enhance more the development of autointoxication than the general intestinal disease itself, and particularly the mucobranous catarrh. But bacteria are not more common in pathological than in normal conditions of the intestine, or, on the other hand, such germs may be of the same kind. The bacillus coli communis is an instance. It does not seem logical to employ bactericides against bacteria which do not exist in pathological conditions, or which also exist in normal conditions.

“Benzonaphthol, associated or not with the salicylate of bismuth, is injurious, and there is not a dyspeptic who does not consume a few cachets of the drug (30 to 60 grains per day). The same may be remarked in regard to patients suffering from intestinal disorders; upon the latter the effects produced are very bad, especially when the salicylate of bismuth is combined with naphthol. Constipation, which ag-

gravates the disorder, is the most grievous consequence.

“Benzonaphthol, in its turn, is at present being opposed and widely discredited as a remedial agent; the researches of Kuhn are contrary to those of Ewald, and prove the uselessness of this product as an antiseptic substance.”

*ABSORPTION OF GUAIACOL BY THE SKIN.*

LINOSSIER and LANNOIS (*Sem. Méd.*, February 7) have studied the absorption of guaiacol by the skin and its elimination by the urine after application to the skin. Their experiments prove that the drug is really absorbed by the skin, as the effect takes place with equal intensity when the patient breathes through a tube opening outside the room in which he is. After the application of 15 grains of guaiacol, elimination by the kidney was already manifest at the end of a quarter of an hour. The proportion of guaiacol contained in the urine reaches its maximum from one hour and a half to four hours after the application. It decreases rapidly after from six to seven hours; in twenty-four hours only traces of the substance can be found in the urine. The quantity of guaiacol eliminated in the urine may amount to one gramme eleven centigrammes, or 55.5 per cent. of the quantity applied to the skin. These researches seem to show that applications of guaiacol may be used to supplement the ingestion or subcutaneous injection of this substance. To quicken the absorptive process, the surface to which the drug has been applied should be covered with some impenetrable material.—*British Medical Journal*, February 17, 1894.

*TRACHEAL IRRIGATIONS IN THE TREATMENT OF CROUP.*

After giving the details of a successfully treated case of croup by the method of tracheal irrigations, the child being placed in an inclined position, GUELPA (*Journ. de Médecine de Paris*, December 24, 1893) draws the following conclusions:

1. Tracheal irrigations, while the child lies with the head lower than the feet, are not only destitute of danger, but are also well borne and easy of application. (In the case described by the author the irrigations were practised by the father of the little patient, with the aid of a servant.)

2. The constant inclined position of the patient in bed facilitates the expulsion of bronchial mucosities, and is a very pr

measure, of great value in the treatment of croup in all the stages of the disease.

3. Abundant irrigations exercise a beneficial influence also in diphtheritic manifestations of the throat and nose; therefore they ought likewise to be practised in cases of diphtheria of the larynx and trachea.

4. Finally, the case that has been described seems to show that, with reference to the etiology and treatment of concomitant or late thoracic lesions of croup, these cannot be looked upon as direct or indirect consequences of respiratory infection, but that the condition of the digestive organs must be considered also; indeed, the case shows that the infection of the bronchi and pleura was of an intestinal origin.

#### HYPODERMIC INJECTIONS OF PHENIC ACID IN THE TREATMENT OF RHEUMATIC AND GENERAL PAINFUL AFFECTIONS.

In an interesting article, ANDRÉ MARTIN (*Les Nouveaux Remèdes*, January 8, 1894) describes several cases of muscular, tendinous, and articular rheumatism, of neuralgia, and other similar affections in which the subcutaneous injections of phenic acid produced satisfactory results. The author believes that,—

1. Phenic acid, hypodermically used, deserves a marked place in the list of nervine remedies.

2. If the phenic acid injections, of the strength of from one to two per cent., act somewhat less rapidly than those of morphine or antipyrin, their efficacy is the same, without presenting the inconveniences of the latter remedies, and without causing either immediate or remote untoward effects.

3. Since they do not act on the cerebral or digestive functions, the injections of phenic acid may be administered at any hour of the day, and in all medical or surgical cases in which the disease is characterized by an element of pain that requires special attention.

4. These injections are indicated not only in particular cases, but may constitute an exclusive and constant mode of treatment in all cases of muscular, tendinous, or articular rheumatism, peripheral neuralgias, and other similar disorders.

The author advises the following combination:

- R Pure phenic acid, 15 to 30 grains;  
Neutral glycerin or alcohol at 90°, 15 to 30 grains;  
Distilled and boiled water, 3 ounces.

Every 16 minims of this mixture contains  $2\frac{1}{2}$  to  $2\frac{3}{4}$  of phenic acid. One to three in-

jections may be administered during the day, as required. These doses are not toxic; but for the sake of precaution, especially in cases of kidney-trouble, daily examination of the urine is sufficient to prevent the occurrence of untoward phenomena.

#### ASAPROL IN THE TREATMENT OF ACUTE ARTICULAR RHEUMATISM.

In a critical article on the treatment of acute articular rheumatism, DUJARDIN-BEAUMETZ (*Bull. Génér. de Thérapeutique*, January 15, 1894) reviews the actions of salicylic acid, antipyrin, and exalgin in this disease, and, after pointing out the advantages as well as the disadvantages exhibited by these drugs, special consideration is given to the employment of asaprol in the disorder in question. Asaprol is a white powder, perhaps of a slightly rosy color, without odor, and having a taste resembling that of the salicylates. It is readily soluble in water and alcohol; in water in the proportion of 100 to 160 of asaprol. The drug is antiseptic and particularly non-toxic. In rabbits, 2.50 grammes per kilogramme of body-weight produces no deleterious effect. Intravenously, however, the fatal dose varies from .75 to .95 gramme per kilogramme of the body-weight. It is eliminated by the urine in the form of sulphuric ether-naphthol, and is there recognized by perchloride of iron, with which it gives a dark-blue coloration. Asaprol is well borne by man, in therapeutic doses of from 3 to 10 grammes (45 to 150 grains), and does not cause dyspeptic or nervous disturbances; it diminishes the pulse and the bodily temperature. It causes neither tinnitus aurium nor skin-eruptions. Asaprol may be given in daily doses of from 4 to 6 grammes (60 to 90 grains), in the form of cachets or in solution. The author recommends the following combination:

- R Asaprol,  $\text{ʒiv}$ ;  
Water,  $\text{ʒxxx}$ .

Sig.—3 to 6 teaspoonfuls during the twenty-four hours, in sweetened water flavored with aniseed or curaçoa.

In this form the drug was administered in thirty-six cases of acute articular rheumatism, of which fifteen cases were of the polyarticular and twenty-one cases of the subacute type of the disease. In the first fifteen cases, there was noticed *considerable amelioration* in one case in twelve hours' treatment, in four cases in one day, in two cases in thirty-six hours, in six cases in two days, in one case in from three to five days, and in one case in from three to

seven days. A cure was obtained in one case in from one to one and a half days of treatment, in two cases in two days, in one case in two and a half days, in three cases in three days, in one case in from three to six days, in four cases in four days, in two cases in from nine to fourteen days, and in one case in ten days. In the twenty-one cases of subacute rheumatism, *considerable amelioration* was observed in thirteen cases in from twelve to thirty-six hours' treatment, in five cases in forty-eight hours, in two cases in from two and a half to three days, and in one case in four days. A cure was obtained in three cases in thirty-six hours' treatment, in one case in forty-eight hours, in three cases in two and a half days, in two cases in from two and a half to four days, in one case in three days, in two cases in from three to four days, in one case in from three to five days, in one case in four days, in one case in four and a half days, in two cases in five days, in one case in five and a half days, in one case in five to sixteen days, in one case in six to thirteen days, and in one case in seven days.

These results seem to show that *asaprol* is not only equal but even superior to the *salicylates*, the rapid amelioration produced by the drug being soon followed by a cure. In none of these cases, nor even in patients suffering from albuminuria, were there noticed untoward after-effects, such as ringing in the ears, intolerance, or similar phenomena. Though considering internal medication as the more important measure in the treatment of acute articular rheumatism, the author appears to regard the external application of remedies as of some service. He refers to the ointment recommended by Bourget, which is as follows:

R Salicylic acid,  
Lanolin,  
Essence of turpentine, of each, gr. xv;  
Lard,  $\bar{3}$ iss.

It is affirmed that half an hour after rubbing with the above ointment salicylic acid appears in the urine. Ruel has used with advantage the following ointment:

R Salicylic acid,  $\bar{3}$ vi;  
Absolute alcohol,  $\bar{3}$ iv;  
Castor oil,  $\bar{3}$ viii.

The admixture of chloroform to this combination is said to enhance the absorption of the salicylic acid, but Dujardin-Beaumetz believes this procedure dangerous and apt to cause serious effects.

#### THE TREATMENT OF CHRONIC HYPERTROPHIC RHINITIS WITH PERCHLORIDE OF IRON.

MOUNIER (*La France Médicale*, January 19, 1894) recommends the use of perchloride of iron in the treatment of chronic hypertrophic rhinitis. In the seven cases reported in his paper, satisfactory results were observed by the author. The drug, he states, is not of much value in nasal obstructions due to persistent chronic hypertrophy of the parts involved, or to polypoid formations, which, although reduced by a prolonged treatment with the local use of iron, are better managed by the galvanocautery. However, in the large majority of cases, the local treatment here indicated (with iron) gives the desired results, since more often than not soft hypertrophies are met with, and these are the conditions that readily yield to the topical applications of iron. These applications are advantageous, since they can be made by all practitioners, and are not followed by any serious complications. The author recommends the use of either of three watery solutions, of the strength, respectively, of 1 to 4, 1 to 2, and 1 to 1, and named Nos. 1, 2, and 3. No. 1 is to be used in the case of infants, No. 2 in older children, and No. 3 in adults in whom No. 2 has failed to produce the desired effects. The remedy can be applied by means of a sound, using or not a nasal speculum.

#### ON SALICYLATED STUFFS.

In an analysis of the various commercial stuffs employed in practical medicine, M. BARTHE (*Arch. de Médecine et de Pharm. Milit.*, February, 1894) never found a greater portion than 3.52 grammes of salicylic acid in 100 grammes of the sample examined. Again, an analysis of several samples of the same salicylated stuff never gave the same proportion of salicylic acid; these proportions varied from 2.30 to 3 grammes in 100 grammes. These salicylated preparations, even by handling them, were found to lose some of the supposed original amount of acid contained in them. For example, a sample of absorbent cotton thought to contain 2.59 in 100 grammes, by being rubbed between the fingers, only gave at one analysis 2.17 of salicylic acid in 100 grammes. The author concludes, from his numerous analyses, that the salicylated preparations do not contain the proportion of five per cent. of salicylic acid, as announced by the various manufacturing French houses, but only three per cent. on an average. Surgeons, therefore, he thinks, before using the-

cylated preparations, should not rumple them up between the fingers, since such procedure tends to diminish their antiseptic richness.

#### MALIGNANT DISEASE OF THE RECTUM.

GAY contributes to the *Boston Medical and Surgical Journal* of March 1, 1894, a useful paper on this topic. He thinks the treatment is palliative or radical. The opinion is gaining ground in this country that the former is preferable in very many patients. The operation or mode of treatment which cures cancer has not been discovered; hence the object of our efforts in the management of the affections under consideration is to give the sufferers all the comfort possible. It does not always seem desirable to prolong life, and yet that is very properly one of the objects of the physician's work.

The treatment of this disease may be considered under three heads,—namely, the alterative, the opium, and the operative methods. Whether one or all of these modes of treatment shall be pursued in any given case depends upon circumstances.

A good illustration of the alterative method was seen in the case of a policeman about forty years of age, who had a malignant ulcerating mass three inches in diameter upon the anterior wall of the rectum above the sphincters. Its location precluded any radical operation and the symptoms did not call for colotomy. He took from 9 to 27 drops of the compound tincture of iodine daily for upward of two years; once or twice a day he took an enema containing from 1 to 2 grains of cocaine. He was thus enabled to do his work as patrolman for the above period. The time finally came when his strength began to fail, and on the day that he was discharged from the force he went into an adjoining room and shot himself dead. He fully understood the hopeless nature of his disease, and the moment that he was disabled he took the management of the case into his own hands.

In view of the fact that this man was always better on resuming the treatment, his physicians could not but think that it had a decided beneficial effect.

It is nearly three years since the writer removed the growth (two inches in diameter) from the rectum of a man forty-seven years of age, by Cripp's operation. It was pronounced malignant by competent authority. The symptoms were pain and hemorrhage. He has taken the iodine daily since the operation, and there has been no return of either symptoms or growth.

Six years ago he removed a similar growth from the rectum of a middle-aged lady, by Cripp's operation. For four years she took Chian turpentine and drank Ypsilanti water constantly. There has been no recurrence of the hemorrhage or of the disease. He believes the cure ascribable to a mistake in diagnosis rather than to the treatment.

Many years ago Dr. Henry M. Field, of Newton, suggested the iodine method of treating malignant disease of the rectum. He thought he had seen beneficial effects from its use; and, so far as regards two cases, which the writer saw with him, he confirms Dr. Field's opinion. For a long time Gay has given the drug to nearly all of his patients with malignant disease, wherever located, provided they could take it without disturbing the stomach. In many cases no benefit was apparent. The rapid growing and malignant ones, as might be supposed, derive less aid from it than others.

The natural course varies so much in different individuals that it is extremely difficult to arrive at reliable conclusions as to the true value of any drug in checking or modifying the new growths. Chian turpentine, condurango, and many other articles have had their day, and have been discarded because they did not stand the test of experience. He claims nothing for iodine. He uses it because it is our duty to give these unfortunate people the benefit of every possible aid, and for this particular purpose there is probably nothing better at present than the compound tincture of iodine.

Under the head of operative treatment there are three measures which require consideration,—namely, Cripp's and Kraske's operations and their modifications, and colotomy. The first is particularly adapted for cases in which the disease is limited to the first five inches of the bowel. It consists briefly in dividing both sphincters and rectum as high as the tip of the coccyx, and then dissecting out the growth or diseased tissues.

Judging from a limited experience, this is a very satisfactory operation. The dangers are shock and hemorrhage. Gay has never seen incontinence of gas or feces to a troublesome degree follow this operation. It is especially indicated for the removal of growths which are limited in extent, movable, and not located over the urethra and prostate.

Kraske's operation is designed for the removal of growths located higher up than five inches, or above the reach of the finger. The sphincters are not divided. The bowel is

reached through an incision over the sacrum and coccyx. The latter bone and a portion of the former is removed. The gut is divided above and below the diseased portion, the latter is removed, and the ends of the healthy bowel are joined with sutures or fastened in the wound, as the condition requires.

The peritoneal cavity is usually opened in this operation, thereby adding another element of danger from extravasation of fæces.

Finally, we come to the most satisfactory operation for the relief of the majority of cases,—colotomy. This is now most frequently done in the left inguinal region, for the reason that the operation is more quickly and easily performed, the wound can be attended to far better by the patient, and the danger is no greater than in the loin. The relief to the obstructive pain or colic is usually complete and permanent. The pressure-pain may still require opiates or other treatment. Many lives are prolonged, and, more than that, they are made comparatively comfortable by this operation. In most cases the patient can keep himself clean and free from odor. A woman upon whom Dr. Bradford performed right lumbar colotomy worked for many months alongside another woman, without the latter ever suspecting that anything was the matter with her companion.

Kelsey's description of the operation is the best one. The incision parallel with Poupart's ligament is made about an inch from the left anterior superior spine. The peritoneal cavity is opened and the colon brought out of the wound. The "bar" is made by joining the edges of the incision with a silver wire passed underneath the bowel. The intestine is then joined to the edges of the wound with sutures, and two or three days allowed to elapse before the bowel is opened. The operation is neither difficult nor dangerous, and in very many cases it is a most satisfactory one to both patient and surgeon.

By way of recapitulation, it may be said that the treatment of malignant disease of the rectum is essentially palliative. Colotomy is indicated to relieve obstructive colic, and it should be done early in order to save the patient's strength. The radical operations are indicated in the early stage, when the growth is limited in extent, free from deep adhesions and infiltration, and not infringing upon the urethra or prostate. Opium is to be avoided as long as possible, and given judiciously, in order that its beneficial effects may not be lost by overdoses before the time comes when it is needed the most. While the disease is incurable,

very much can be done by judicious management to make the patient's life endurable and his death peaceful and easy.

#### *SINGLE LIGATION OF THE CORD IN OBSTETRIC PRACTICE.*

According to the *Boston Medical and Surgical Journal* of March 1, 1894, NGUYEN KHAC CAN bases his opinion of the superiority of a single ligation upon his observation that out of sixty-eight cases of labor with double ligation of the cord, there were four cases of retention of the placenta, and out of one hundred and forty-six cases with single ligation, only two cases of retention. The duration of the third stage with the double ligation averaged sixty-four minutes, while with the single it was but twenty-seven minutes.

The author believes that a rapid diminution in the size of the placenta, due to the free escape of the intraplacental blood, favors retroplacental hemorrhage and consequent complete separation of the placenta, and that it further lessens the obstacle to its escape from the uterus and vagina by the resulting decrease in size. He recommends that double ligation of the cord should be reserved for cases of twin pregnancy. While we think that there is a question as to the correctness of the author's reasoning on the first point, there can be no doubt as to the advantage of diminishing the size of any body which is to pass the os uteri, and we have ourselves noticed a greater ease of delivery of the placenta in cases in which but one ligation had been applied.

The suggestion of Nguyen Khac Can is certainly of value. It should be easy to prevent untidiness by catching all the intraplacental blood in a suitable basin, but the determination not to check intraplacental hemorrhage, of course, implies a careful palpation of the uterus before the cord is cut, and an absolutely positive elimination of the possibility of a twin pregnancy.

#### *THE RADICAL CURE OF HYDROCELE.*

In the *Boston Medical and Surgical Journal* of March 1, 1894, GARVIN writes on this subject. He asserts that the different methods used for the radical cure of hydrocele are antiseptic incision, excision of a part or the whole of the sac, and injection; all other methods are now obsolete. It is with the last-mentioned method that this paper has to deal. The open incision, with or without excision of the sac, means the administration of an anæsthetic, detention in bed for a varying period from

week to four, while to undergo an operation has considerable effect on the minds of most of our patients.

There are cases where the open incision is the only operation to be considered: where there is a question of diagnosis; where a hernia exists; where injection has failed,—congenital hydrocele; where the sac is much thickened. In all of these some form of open operation is called for.

There is a large class that can be successfully treated by injection. Perhaps it is well to inquire why injection has so often failed to cure the disease.

Let us hear the explanation as given by Jacobson for the many failures: (1) The use of too weak a solution; (2) not bringing the solution in contact with the whole of the sac; (3) not withdrawing all the hydrocele fluid; (4) injecting large hydroceles immediately after they are emptied; (5) making use of injections in unsuitable cases.

No simple, uncomplicated case of hydrocele ought to be treated other than by injection. The use of tincture of iodine, the simple as well as the compound, is too often followed by failure to urge its use, which is often attended by a scene, patients often fainting and suffering from griping pains, retraction of the testicle, nausea, and even vomiting; unpleasant things to have happen in one's office. Since about six years the writer has treated all suitable cases of hydrocele by injecting half an ounce of a solution composed of equal parts of carbolic acid, alcohol, and glycerin; a small bulb syringe answers very well. A little care is necessary in the use of the solution. Protect the skin surrounding the canula with a little gauze or absorbent cotton, so as to avoid the burning sensation so easily produced on the tender skin covering the scrotum; allow the fluid to remain. The injection is practically painless, and no unpleasant effects follow its use. Patients are allowed to attend to their ordinary business, and in from two to four weeks the acute hydrocele disappears. Since using this method the writer has seen only one case relapse. The method has proved so effective, and with none of the drawbacks of other methods, that he brings it forward. He has never employed carbolic acid, as recommended by Dr. Levis.

#### TREATMENT OF ITCHING.

In a paper on this subject, BRONSON says of those drugs which give relief by acting as *sensory stimulants*, that the kind of stimulation which it is intended by these to effect is not of

that general character which simply augments the common irritability of the skin, but it tends rather to enhance its higher and perceptive sensibilities. By its action the function of the sensory nerves is so improved that sensations of contact or temperature, which through obstruction are exaggerated into the fret of itching, find freer channels of escape and a more normal interpretation in the sensorium. It is more especially in such forms of pruritus as are associated with hypopselaphesia as a predisposing cause—as, for example, in pruritus senilis—that remedies of this class are indicated. An example of this kind of stimulation has already been alluded to in speaking of the mechanical modes of relief that may be substituted for scratching. It probably constitutes an incidental effect in the action of various antipruritic remedies more properly belonging to other classes. There is one, however, that would seem to legitimately belong here,—namely, electricity, whether in the form of galvanism or faradism. Under one form or the other, this agent has sometimes proved to be of decided benefit. Perhaps the most effective agents of this class are those that act upon the nervous centres. Thus, strychnine, in those cases of pruritus which we may call atonic, is a remedy of value. Cannabis indica, which is a decided stimulant to the nervous centres and the higher sensibilities, may owe its efficacy in this disease quite as much to this fact as to any anæsthetic effect upon the commoner sensation of the skin. Its action in pruritus, therefore, would be analogous to that which has given it its reputation as a remedy for sexual impotence.

We have seen that a frequent cause of cutaneous pruritus is reflex irritation. Herein is discovered another factor in the *indicatio morbi*. Reflect the irritation back to its original source, or taking the initiative as aggressor, invade some inoffensive region that may be made to sympathize with the skin and make it bear a part of the skin's burden. It suggests our fourth class of remedies.

Of the *substitutive irritants*, the rationale of the good effect often witnessed in cutaneous irritations from cathartics, hepatic stimulants, and diuretics is that by these means a remote disturbance is created into which is diverted a portion of the cutaneous excitement. It is a method of treatment that can seldom be spared, and the aid thence derived may make all the difference between success and failure of local and more direct measures. But in pruritus the sympathetic substitution is not always effected between the skin and a remote or interior part,

but between different portions of the tegumentary surface, and, what is more, between different kinds of sensation in the skin. Pain is antipathic to pruritus, and one may be substituted for the other. The effect of smarting or stinging applications in relieving pruritus is thus explained. It doubtless explains part of the effect of thymol, chloroform, hot water, and other burning or pungent applications. It is analogous to the action of the "sensory stimulants" described above, where tactile impressions, which, on account of the impaired or occluded media, tend to degenerate towards common sensation, are deflected into the channels of higher special sense. A similar interchange occurs, as we have already seen, between the contact sense and the sense of temperature. Both cold and heat beyond a certain point annul the sensation of itching. Slight changes in temperature often evoke it, but so long as the sense of temperature remains at all noticeably affected, it dominates the itching, which, for the time being at least, remains in abeyance. We sometimes avail ourselves of this substitutive action by using cold applications, but the stimulation which these cause is apt to aggravate the pruritic excitement afterwards. But a remedy which is one of the best palliatives of itching that we have, and which is especially noteworthy in this place, is menthol, together with the peppermint preparations generally.

Menthol is commonly referred to as an anæsthetic, but it relieves itching as it relieves pain, not by direct inhibitory action on the molecular movements of the sensory nerves, as do the true anæsthetics, but chiefly, if not solely, through substituting an exaggerated temperature sense for the perturbed sense of contact, or for the sensation of pain. Goldscheider, who has carefully investigated this subject, attributes the sense of coolness that follows the application to the skin of menthol or other peppermint preparation to a specific action on the special nerves of temperature, causing what is virtually a hyperæsthesia of the temperature sense. He also found incidentally that when a portion of the skin—as, for example, the forehead—had been rendered insensible to cold by application of ice and then afterwards mentholized, the sensations of burning, pins and needles, and the like, which the cold produced, remained unaffected in spite of the menthol, from which it is inferred that the latter is not a true anæsthetic. Of its antipruritic virtues there can be no question. It is usually employed in alcoholic solutions (5 to 10 grains to 1 ounce) and may be used in

ointment. It is also with advantage combined with salol or thymol.

A fifth class of remedies often indicated in pruritus essentialis may be designated as follows:

Of the *alteratives of cutaneous nutrition*, he says they include not only absorbent and antiscatarrhal remedies to remove the products and curtail the processes of incidental inflammations which may act as contributory causes of the itching, but such agents as tend to control blood-supply and overcome hyperæmia. In this way act diaphoretics, and possibly diuretics, as well as by their substitutive and eliminative or depurative action. Thus, it is probable that jaborandi, which is extolled by so many writers for its efficacy in this disease, acts in all three ways. It determines excitement to the secretory instead of the sensory organs of the skin; it promotes the elimination of noxious matters which are irritants to the nerves; and, finally, the diaphoresis depletes the blood-vessels. This drug is especially useful when the skin is hot and dry, and where it has become the depot of noxious materials deposited from the blood,—as, for example, in the itching of icterus.

The local remedies belonging to this class include certain resinous or tarry substances, which are especially indicated in associated catarrhal conditions and have a certain controlling effect upon hyperæmia. Such are ichthyol (five to ten per cent.), tumenol (twenty-five per cent. or pure), occasionally tar, resorcin (three per cent.), and benzoic acid or benzoïn.

When considering the etiology of pruritus, one of the incidental causes of the deranged function of the sensory nerves is ascribed to a condition of impaired nutrition in the skin with defective metabolism. In a condition such as this it is a commonly-accepted opinion that agents which promote oxidation are especially indicated. Now it is a significant fact that a large proportion of the remedies that allay itching are oxidizing agents; while, on the other hand, a reducing agent rarely, if ever, has any direct antipruritic effect. It is the keratolytic substances, which are also, as a rule, oxidizing agents, from which we largely select our antipruritic remedies. Such are the whole group of antiseptics, the mineral and vegetable acids, and also the alkalis. The oxidizing effect may in many instances be subordinate to other actions they possess, but a property common to them all can hardly fail to have some therapeutic significance.

Led by these considerations, it seemed

author that the solution of hydrogen peroxide should be an appropriate remedy for pruritus, and he has had abundant verification of this fact in the last few years. It may be used as a toilet wash two or three times a day. In place of this, and perhaps with equal benefit, he has used an aqueous solution of ozone, known commercially by the hybrid name "aquozone."

The final indication for treatment which the etiology suggests relates to the hyperkinesis of the *erectores pilorum* muscles. Inasmuch as the spasm affecting these muscles is always secondary to some other condition, measures which relieve the latter will generally be the ones best calculated to dispose of the former, and ordinarily no more special treatment of this contributory factor is needed. But to be complete, our classification of remedies should embrace one more class.

Among the internal remedies, useful motor depressants are gelsemium and *jaborandi*, and it is very possible that to this fact they owe in some measure their antipruritic effects. Another remedy which, though recommended more especially in urticaria, should be mentioned here is atropine. It is probable that the good effect of this drug in urticaria, when used in full doses, such as are always required to produce this effect (from  $\frac{1}{16}$  grain upward), is due not to the primary, but to its secondary, action. The primary action attendant upon the smaller doses tends to excite muscular contractions and cause increased vascular tension. In its secondary action its effect is just the contrary of this: the muscles relax, the vessels are dilated. It is doubtless through release of tension in the cutaneous muscles that this drug acts so favorably in the urticarial hyperkinesis.

Of the local remedies belonging to this class, the first place unquestionably belongs to the hot-water applications. Here, also, might perhaps be included certain local sedative remedies, such as hydrocyanic acid, the cyanide of potassium, conium juice, tincture of arnica, and chloroform, all of which are decided depressants of motor action.

Having thus in a general way met the various indications for treatment in pruritus essentialis, it remains to briefly apply the therapeutic principles laid down to certain special forms of the disease. It must be confessed that, however clear these principles may appear in the abstract, to apply them in the concrete—i.e., to individual cases—is not always easy. Often, and in large degree, we must rely on empiricism in its better sense. To

know the rationale of things is most desirable, but in practice experience is often truer than theory.

Thus, in pruritus senilis, while theory suggests more especially the sensory stimulants described under C, so complex often are the morbid conditions involved in this form of the disease that recourse must be had to remedies of very diverse nature. In some respects theory and experience here correspond. The successful employment of faradism in senile pruritus, that has received abundant testimony, is scarcely susceptible of any better explanation than that afforded by the theory of its restoring or stimulating an impaired sensory function. It by no means always succeeds, but in uncomplicated cases it rarely fails of good effect if persisted in. It has seemed to the writer that it was often effective when applied only to the spine and not directly to the pruritic surfaces. It is best administered by means of a brush electrode. The cold douche is another remedy in the same line that is sometimes of benefit, and is best used in the morning. In one or two cases patients have assured him that prolonged relief was obtained by certain frictions of the skin at night, as with the rough mitten sometimes used in bathing. Such a remedy, however, could rarely be recommended as a safe one. For internal use the strychnine and *cannabis indica*, which are stimulants to the nerve-centres, are appropriate remedies, and have already been referred to. The tincture of *cannabis indica* may be given in doses gradually increased from 10 drops to 1 scruple or  $\frac{1}{2}$  drachm, three times a day, unless it should disturb the digestion. The *indicatio causalis* in this disease opens a wide field for therapeutic measures. Those included in the class of "alterations of cutaneous nutrition" are particularly important. Internally, antilithic remedies—alkalies, diuretics, and cholagogue cathartics—are required to meet special indications. Locally, we may employ the alkaline baths, the hydrogen peroxide, and the oxidizing substances of the antiseptic group. Nor can the sedative applications be dispensed with. Which one will answer best can often only be determined by trial. A ten-per-cent. solution of salol in benzoinol is of some use; the carbolic oil mentioned above is more powerfully antipruritic, but requires caution. It is best suited to limited areas of itching. Menthol also acts admirably in many cases, either alone or, what is better, in combination with some emollient substance. If too strongly or too frequently applied, it is liable, like carbolic acid, to irritate, and thus

render the skin more sensitive. A remedy highly extolled by the English is liquor carbonis detergens (a three-per-cent. solution in water).

In pruritus hiemalis an all-important measure of treatment is protection against cold. The sole cause of winter pruritus, aside from a special predisposing hyperæsthesia, is lowered temperature. The first cold day evokes it, and, after raging through a succession of cool days, the first warm day will make it disappear till again the weather changes. The temperature effect may be forestalled to a certain extent by protecting clothing. A minor point, though by no means an unimportant one, is, that in making changes of clothing, the undergarment should remain as light as that worn during the warmer weather. If wool is required, it should be worn outside this thin undergarment. Sometimes it is well to bandage the legs (where the trouble is always worst), at least for the latter part of the day. At night a wet pack for this portion of the body often gives much relief. A five-per-cent. salol superfatted (Eichhoff's) soap may be moistened and smeared over the itching surfaces, where it is allowed to dry on. The surest relief when the itching areas are of limited extent (and such often is the case) is afforded by the antipruritic oil mentioned above. Each morning care should be taken to dress any excoriated or inflamed spots, due to scratching, with some healing, emollient application, such as the Lassar paste. Otherwise there is much danger of eczema being developed. Indeed, it is possible that a large proportion of the chronic eczemas of the legs owe their first inception to this very cause,—i.e., the scratching occasioned by pruritus hiemalis.

In pruritus of the genito-anal region, while all possible is being done to remove or abate any accidental cause which may be discovered, the choice of direct antipruritic remedies will depend much on the nature and complications of the case. Special treatment is required for cases associated with eczema or other inflammatory disease. For the itching, perhaps no remedy is more generally useful than hot water. The patient squats over a vessel in which there is water as hot as the hand can bear, and after a little the temperature can be tolerated still higher. With a handkerchief held as a swab between the fingers, the water is sopped on for a period of three or four minutes. The part is then gently dried with a soft cloth and well powdered with talc or other inert substance. In all of the forms of pruritus in this region carbolic acid is of very great value; but, as al-

ready intimated, to be of much avail it must be used strong. The above-mentioned oil is especially useful in these regional forms, but should not be used too frequently nor where much inflammation prevails. Menthol in a thin ointment (5 to 10 grains to 1 ounce), or the peppermint-water, is also extremely useful, and salol may be added with advantage. All of them should be followed by copious applications of a soothing powder. In some cases, more especially where the parts are sore or abraded from long scratching or rubbing, the greatest relief will be afforded by cocaine, whether in a four-per-cent. watery solution or, what is better, in some soothing emulsion or thin ointment.

For pruritus vulvæ some of the special remedies advised are painting the parts every night with compound tincture of benzoin, or, in some cases where the surface is thickened from long irritation, occasionally touching the affected region with a rather strong solution of nitrate of silver (1 scruple in 1 ounce of water). Many authorities have advised applications of corrosive sublimate ( $\frac{1}{4}$  to 1 grain in 1 ounce of water), or the following prescription, recommended by Bartholow, will sometimes be found useful:

R Hydrarg. chlor. corros., 1 part;  
Alum, 20 parts;  
Starch, 100 parts;  
Water, 2500 parts.

When the itching affects the mucous membrane it can generally be relieved by cocaine.

For pruritus scroti, Crocker advises painting the part with a solution of silver nitrate (10 grains to 1 ounce) in sweet spirits of nitre. In inveterate cases he has sometimes employed, with considerable success, a method of treatment first suggested by Vidal. It consists in scarifying the entire itching and usually thickened surface with Squire's scarifier or an ordinary scalpel. The incision need not go much beyond the epidermis. But there is an advantage in drawing a little blood. Afterwards the part is dressed with a thin layer of Lassar paste, which may contain a little cocaine. The layer should be thin, for it is a fact of common experience that ointments are rarely well borne in pruritic affections of the genito-anal region.

The remedies most useful in pruritus ani are the same generally as those for the vulvar and scrotal forms. Sometimes relief can be obtained here only through substitutive irritants. A liniment containing chloroform or camphor in sufficient strength to cause considerable

smarting will occasionally give relief to the intense itching which can be secured in no other way. A method suggested by Allingham would perhaps belong more properly to the class of sensory stimulants. A bone plug an inch and a half long and about as big in diameter as the end of the forefinger is slipped into the anus on retiring, and retained in position through the night by means of a compress.

#### PERMANGANATE OF POTASSIUM AS AN ANTIDOTE TO MORPHINE.

In the February number of the *THERAPEUTIC GAZETTE* there was a short leading article upon the use of permanganate of potassium as an antidote for morphine. Since that time Dr. MOORE has published his studies concerning this matter in the *Medical Record* of February 17. The results obtained by him are of very considerable interest and may be summarized as follows:

In case of poisoning by any of the salts of morphine, 10 or 15 grains of the antidote dissolved in 6 or 8 ounces of water should be administered at once, and repeated at intervals of thirty minutes, three or four times, or even more often. Permanganate of potassium, as well as the salts of manganese, are comparatively harmless, even if given in large quantities. Moore has poured into the stomach of a rabbit weighing four pounds a solution of 5 grains of permanganate of potassium in 2 ounces of water, and one hour later 2 grains more dissolved in 1 ounce of water, without noticing any toxic effects whatever. One ounce of the sulphate of manganous oxide has caused only brisk catharsis (Dr. Thompson).

In cases of poisoning by the alkaloid itself or by tincture of opium (*laudanum*), also by opium, it is advisable to acidulate the antidotal solution with diluted sulphuric acid, or, in the absence of this, with some white vinegar (not red vinegar), by which the insoluble morphine will be at once converted into the soluble sulphate or acetate.

The author believes that the administration of permanganate will be of beneficial effect even after absorption of the morphine has taken place. This statement he bases on the following:

Professor Edward Hitzig, of Halle, two years ago, proved beyond a doubt that morphine which was injected subcutaneously into dogs was secreted by the glandular lining of the stomach. Hitzig succeeded, by washing out the stomachs of animals that had received morphine subcutaneously, in obtaining fully

one-half of the injected amount during the first hour after the injection. It is therefore a logical necessity that an antidote which acts instantaneously must destroy in the stomach a certain amount of poison that got into the circulation either through hypodermic injection or through absorption by the stomach, for it is evident that the same circulation which conveys a poison from the peripheral parts of the body to the stomach must also bring back to the latter a part of the poison which previously was absorbed by it. The writer has obtained some highly encouraging results from experiments on rabbits. As to the effect of permanganate of potassium upon other alkaloids, he briefly enumerates the results he has obtained.

*Atropine*.—1 grain of sulphate of atropine dissolved in 1 ounce of water, added to 1 grain of permanganate of potassium in  $\frac{1}{2}$  ounce of water. Color, purple, as if the solution contained only permanganate of potassium. After four hours, color still purple, no change from original permanganate color; 1 drop instilled into a person's eyes widely dilates the pupils in a few moments, mydriasis lasting over twenty-four hours. After eight hours, color dark red, taste intensely bitter; addition of sulphate of morphine gives the characteristic reaction (dark precipitate, colorless liquid above it). After twenty hours, color dark brown, taste intensely bitter; addition of morphine gives the characteristic reaction. Thus, permanganate of potassium has practically no effect upon atropine.

*Cocaine*.—1 grain of cocaine muriat. to 1 ounce of water, added to 1 grain of permanganate of potassium in  $\frac{1}{2}$  ounce of water. Color, purple, as if the solution contained only  $Mn_2O_4K_2$ .

Four hours later, color dark red, taste intensely bitter; 1 drop instilled into a person's eye causes decided mydriasis, lasting half an hour; addition of morphine gives the characteristic reaction. Eight hours later, color grayish red, taste bitter; applied to the pharynx, distinct difficulty in swallowing noticeable; dark precipitate on the addition of morphine. Practically no effect on cocaine.

*Veratrine*.—2 grains of veratrine muriat. to  $\frac{1}{2}$  ounce of water, added to 2 grains of permanganate of potassium in 1 ounce of water. Color, purple; ten minutes later, purplish red; fifteen minutes later, dark brown; precipitate on addition of acetate of morphine; thirty-five minutes later, precipitate with brownish liquid above, the latter turning light on the addition of acetate of morphine, and if applied to the nasal mucous

membrane causing violent sneezing (one of the characteristics of veratrine). Useless in veratrine-poisoning.

*Pilocarpine*.—2 grains of pilocarpine muriat. to 2 ounces of water, added to 2 grains of permanganate of potassium in 1 ounce of water. Color, purple; after, five minutes, still purple; after forty minutes, carmine.

After seventy minutes, color carmine; 1 drachm injected subcutaneously into a rabbit causes lachrymation, salivation, profuse perspiration, irregular rapid breathing (160), three or four copious watery discharges.

After three hours, color still red; addition of morphine gives the usual reaction. Practically without effect on pilocarpine.

*Aconitine*.—2 grains of aconitine to 2 ounces of water, added to 2 grains of permanganate of potassium to 1 ounce of water. Color, purple. After stirring for two minutes, same color.

After two hours, color unchanged;  $\frac{1}{2}$  drachm (2 cubic centimetres) injected into a full-grown rabbit; animal restless in a few moments, turns his head to the side, makes rapid swallowing motions, salivates, is evidently nauseated; difficult, irregular breathing, tremor, opisthotonos; animal lies on its side, apparently *in extremis*, but after ninety minutes symptoms begin to abate.

After twenty-four hours, color still reddish purple. Dark precipitate by addition of morphine. No effect on aconitine.

*Strychnine*.—1 grain of strychn. sulphat. to 1 ounce of water, added to 1 grain of permanganate of potassium to  $\frac{1}{2}$  ounce of water. Color, purple; after five minutes, red; after fifteen minutes, dark brown, intensely bitter; after thirty minutes, same color, taste intensely bitter. Addition of morphine, black precipitate, colorless liquid above.

This treatment could not be depended upon in strychnine-poisoning, if the stomach should contain organic matter, which is the rule.

#### DIGITALIS AND ACONITE IN INFLUENZA.

BURTON contributes to the *Medical Press and Circular* of January 31, 1894, a paper upon this subject, in which he states that the following rules of treatment should be carefully followed. He claims that it is the result of his experience in eight hundred cases of influenza treated during the recent epidemics.

In the treatment of typical or, indeed, any form of influenza, the patient should be iso-

lated, preferably in a darkened room sufficiently airy. The room temperature should be maintained at from 63° to 65° F. The bed-clothes should consist of sheet and blankets, no counterpane, and should be graduated in thickness inversely to patient's temperature. Patient's feelings may be considered to some extent on this point, but it is well to remember that the feeling of chilliness which often accompanies very high temperatures is relieved by cooling the surface. It is common to find a patient with a temperature of over 103° F. or 104° F., and rising, covered with a sheet, three or four blankets, a cotton counterpane, and an eider-down quilt.

From the first the patient must be saved all possible exertion; this point is of the utmost importance during treatment.

The horizontal position should be insisted on, and when it becomes necessary to raise the patient to a sitting posture, this should be done deliberately and gently.

The feet should be frequently examined by the nurse, as they are often cold at first, even when the temperature by the mouth is high.

From the first the diet should consist of cold milk, plain or mixed with an equal quantity of barley or soda-water. Beef-tea and other meat infusions are discarded as useless during the pyrexial stage. Plain boiled water may also be taken cold at intervals, but this should not take the place of milk. After the pyrexial stage alcoholic stimulants are most useful. Alcohol distinctly antagonizes the slowing effect of the remedies on the heart's action, and so materially retards the antifebrile influence of the aconite and digitalis.

The patient should be kept free from all excitement, and should be spoken to as seldom and as little as possible.

After placing the patient in bed the following mixture is given:

R Tinct. digitalis,  $\mathfrak{m}\text{x}$ ;  
Tinct. aconiti,  $\mathfrak{m}\text{iiss}$ ;  
Liq. ammon. acetat.,  $\mathfrak{f}\mathfrak{z}\text{iiss}$ ;  
Aque, ad  $\mathfrak{f}\mathfrak{z}\text{viii}$ . M.

Sig.—1 tablespoonful to be taken directly, and repeated every hour until four doses have been taken; then every two, three, or four hours, as directed.

If there be a marked and pretty rapid temperature fall (say from 104° to 102° F. in the first four hours) it may not be necessary to give the fifth dose until three or four hours after the fourth. In deciding this point, regard must be had to the effect of the drugs upon the heart's action, which should have been carefully examined in the first instance. As a rule, it is

advantageous to push the digitalis steadily, every two hours, after the fourth dose has been taken, until the temperature has fallen to 99.4° or 99° F., when it should be discontinued. Under this treatment the temperature falls, in the great majority of cases, to 99° F. or lower within twelve hours from the time the first dose is taken, and does not rise again above normal. Frequently it reaches normal or lower in six hours or less. In one typical case—*i.e.*, without discoverable complications—the patient (a robust, healthy man, aged twenty-three) had his temperature reduced from 105.6° F. in seven hours. He had been taking (owing to the culpable negligence of the attendant) double the dose prescribed (or 20 minims of digitalis with 5 minims of tinct. aconite) every hour. This patient felt well but weak after the seventh dose, and recovered quickly.

*OUR PRESENT KNOWLEDGE OF THE  
CURE OF MALARIA BY MEANS  
OF QUININE.*

PROFESSOR C. BINZ (*Cent. f. die Med. Wissen.*, No. 2, 1894) states that just twenty-six years ago he opposed, in the pages of the *Centralblatt*, the then generally-accepted theory that the curative action of quinine in malaria is developed through the nervous system, and propounded the theory that quinine in all probability acts as a protoplasm poison on the pathogenic micro-organism, at that time undiscovered, which is at the root of all paludism. It has now been discovered that all forms of malarial fever are brought about by organisms of the genus *amœba*, which penetrate the bodies of the red blood-cells, at whose expense they increase in size, finally sporulating and destroying their host. Laveran, who first discovered and described the parasite of tertian ague, also investigated the action of quinine on that organism, and found that when microscopical preparations of the parasite were treated with quinine, the vitality of the disease-germ was speedily destroyed, a fact which has been substantiated by Marchiafava, Celli, Grassi, and Feletti. The influence of quinine on the malaria parasites has also been studied by examining the blood of malaria patients before and after the exhibition of the drug. In this instance the investigations of Laveran, Romanoffsky, Bacelli, Golgi, Marchiafava, and Bignani established the fact that the parasites were killed by the quinine absorbed into the blood.

Dr. Mannaberg, who has recently investigated this question in the malarial districts of Dalmatia, Istria, etc., finds, among other

things, that about three hours after the exhibition of from 7 to 15 grains of quinine, the amœboid movements of the amœboid form of the parasite of tertian ague slacken to a very perceptible degree, and that after a lapse of a further period of three to six hours, the number of parasites in the blood of the patient greatly diminishes, while many of those still left are torn and mutilated. On the full-grown parasite of tertian ague quinine either produces a complete cessation of all movement in the pigment, whereby the parasite acquires a glittering, cloddy appearance, as though coagulation had set in, or else dropsical swelling is set up, or, finally, the parasite falls to pieces. Shortly after the exhibition of quinine, medium-sized parasites of tertian ague develop intense activity. It appears that quinine possesses a stimulating action before causing coagulation and immobility. This phenomenon has also been observed by Bacelli. According to Golgi, the medium-sized parasites of quartan fever acquire a glittering appearance and tendency to shrivel when the patient receives quinine internally; the large forms, however, become distended, their pigment exhibits lively oscillatory movements, and they frequently contain vacuolæ or abortive spores.

About three hours after the exhibition of a dose of 7½ grains of quinine, the nucleoli of some of the amœbæ of the milder forms of true quartan had either partially or entirely lost their tinctorial characteristics. After twelve hours of the treatment stainable nucleoli were hardly met with at all, most of the parasites having broken up into irregular fragments.

From these and other experiments it is evident that the amœba of malaria is not only visibly enfeebled by the presence of quinine in the blood, but that its capacity for producing viable spores is greatly diminished.

In those forms of malaria which are not curable by quinine that drug has no effect whatever on the parasites present in the blood. Bacelli, however, has found that many such severe forms which defy the ordinary method of treatment may be speedily cured by injecting the usual dose of quinine into a vein.

In spite of certain differences on minor points, Mannaberg and the other investigators one and all agree that quinine is a direct poison for the malaria parasite, and that the therapeutic doses employed are non-injurious to the cells of the human organism. Any assistance from the nervous system in the process of cure is neither evident nor necessary.

With regard to the prophylactic action of quinine, it is to be noted that the drug disap-

pears very gradually from the blood and in an almost unaltered condition. By this means any young amœbæ and spores are kept in constant contact with the drug and are thereby checked in their further development. As to the part played by the leucocytes, it appears that phagocytism is prominent in cases of spontaneous cure of malaria, but not when quinine is employed.—*Provincial Medical Journal*, March 1, 1894.

#### ON MEAT DIET FOR GOUT.

From time immemorial excessive meat eating has been considered the chief cause of gout. As medical experience corroborates this view, until quite recently gouty subjects were advised to reduce their consumption of meat to the smallest possible quantity; but a few years ago Dr. Emil Pfeiffer advocated the contrary system, and based his conclusions on the quantity of uric acid observed in the case of five healthy and six gouty persons subjected to the particular diet prescribed by him. According to Pfeiffer, this diet consisted chiefly of albuminous substances, such as meat and eggs, and also of fat and green vegetables, while carbohydrates, more especially starch and sugar, were scrupulously avoided; and analysis proved that the secretion of urea and uric acid was increased and the fluids of the body rendered as alkaline as possible. Pfeiffer concluded from the results of the analyses in these eleven cases that healthy individuals excrete more uric acid than gouty patients; but all his subsequent investigations, as well as about two hundred determinations of the uric acid excreted by one of Mordhorst's patients, gave a contrary result. (The uric acid was determined according to Heintz's method.) As a matter of fact, sufferers from gout excrete, on an average, more uric acid than healthy persons, and a strictly meat diet, so far from rendering the fluids circulating in the body more alkaline, has the opposite effect. It is a well-known fact that the power possessed by a fluid for dissolving uric acid depends upon its alkalinity. Unfortunately, although we can readily render the urine alkaline, it is extremely difficult to render those tissues which are predisposed to the deposition of uric-acid deposits neutral, much less alkaline. The urine of a puppy receiving a daily ration of a couple of rolls and about eight ounces of milk is invariably slightly alkaline, whereas that of a similar puppy, only receiving meat as well as milk, never gives anything but a strong acid reaction.—DR. MORDHORST, in the *Provincial Medical Journal*, March 1, 1894.

#### VALERIANATE OF AMYL.

BLANC (*Rev. de Thérap. Méd.-Chir.*, December, 1893) describes valerianate of amyl, which is the odoriferous principle of the apple,—that is, the essence extracted by distillation together with alcohol. Cider has long been believed by the laity to have some effect on calculous formations, and this seems to be borne out by the fact that valerianate of amyl really has some solvent action on cholesterin. It is a colorless liquid, of pleasant taste when taken in small quantities, and can be prepared in the laboratory by the action of valerianic acid on amyl alcohol; 1 grain of cholesterin is dissolved by  $4\frac{1}{2}$  grains of valerianate at  $37^{\circ}\text{C}$ . and by 3 grains at  $40^{\circ}\text{C}$ . Physiologically the action resembles that of ether, but the special qualities lie in its being a stimulant and sedative to the liver in cases of hepatic colic. It not only immediately subdues the attack, but it prevents recurrences. If the stomach is irritable, it may be necessary first to employ sulphuric ether, following this with two to three capsules of fifteen centigrammes each, given every half-hour until the crisis is past, and continued at longer intervals during the following days. In nephritic colic the drug acts as an antispasmodic and general stimulant only, but no effect is produced on the renal calculi. Muscular rheumatism is frequently relieved, and much benefit is also derived from its use during menstrual uterine contractions. As a sedative, it is of value in hysterical manifestations. Its toxic properties being very slight, as many as five to six capsules can be taken daily, but it is necessary to guard against gastric disturbance.—*British Medical Journal*, March 10, 1894.

#### CHLORALOSE.

J. OHMJELEWSKI (*Medicinskoje Obosrenje*, No. 24, 1893) has tried chloralose in seventeen cases of mental disease, including simple and periodical mania, senile dementia, paranoia, melancholia agitata, etc. The drug was given in doses of from one-half to one grain. Sleep was induced, as a rule, in about forty minutes after administration, and lasted from four to ten hours. In three cases transient tremor of the upper limbs was observed before the patient fell asleep. In five cases considerable perspiration occurred. No ill effects as regards the gastro-intestinal canal were noticed. In two cases considerable excitement followed the administration of the drug. On the whole, the author looks upon chloralose as a valuable remedy in cases of mental disease, and one

especially likely to be useful where chloral and sulphonal are contraindicated.—*British Medical Journal*, March 10, 1894.

#### MASSAGE IN PRURIGO.

MURRAY, of Stockholm, found (*Hygiea*, 1889) that massage had a good effect in a case of prurigo in a boy aged eleven; the procedure had no effect on the process, but relieved the distressing itching. HATSCHEK (*Arch. f. Derm. u. Syph.*, xxv., Jahrg., 1893, Heft vi. p. 931) had the opportunity of trying the method in Kaposi's clinic in eleven cases (nine males, two females). Of these, seven were suffering from prurigo ferox, four from prurigo mitis. Most of them were young (fourteen to twenty-one years of age), but one was aged sixty-two. Nine were treated exclusively by massage; in two cases this was for a time supplemented by carbolic-acid pills. To exclude sources of fallacy, dry massage was used in the form of simple effleurage. Stroking was moderately firm, and was made in a centripetal direction. The duration of each sitting was at first ten to fifteen minutes; after a time this was shortened to five and later to three minutes. In all the cases itching was markedly relieved; in some after two or three sittings, in others not till after some weeks. It is pointed out that the rapidity of the effect bore no relation to the severity of the symptoms. That treatment is more effectual if vaseline is employed. The method has no direct effect on the disease process, but it was noticed that new nodules, developing while the patient was under treatment, itched less than had formerly been the rule and rapidly disappeared. In some cases recurrence of the pruritus took place. To prevent this, massage must be continued to a greater or less extent throughout the patient's life. In other conditions, such as urticaria, psoriasis, etc., massage did no good, and sometimes seemed to do harm.—*British Medical Journal*, March 10, 1894.

#### FOR LARYNGEAL PHTHISIS WITH DYPHAGIA.

R Cocainæ hydrochloratis, gr. x;  
Acidi borici, gr. iv;  
Glycerini, m̄xv;  
Aquæ destillatæ, q. s. ad f̄i.  
Misce.

Sig.—To be applied to the throat when necessary.

—*Practitioner*, February, 1894.

#### ANTIPYRETIC PILLS IN PHTHISIS.

R Pulveris digitalis, gr. i;  
Quininae hydrochloratis, gr. iss;  
Pulveris opii, gr. ss.  
Misce et fiat pilula, No. i.  
Sig.—One to be given every six hours.

—*Practitioner*, February, 1894.

#### A TONIC MIXTURE.

R Wine of kola,  
Wine of cinchona,  
Wine of gentian,  
Wine of colomba, of each, ℥viii;  
Fowler's solution, gtt. x;  
Tincture of nux vomica, gtt. v.  
A wineglassful after each meal.

—*Journal de Médecine de Paris*, January 4, 1894.

#### THE ADMINISTRATION OF SALICYLIC ACID BY THE RECTUM.

The *Journal de Médecine de Paris* for January 4, 1894, recommends the employment of salicylate of sodium by injection into the rectum in those cases in which the stomach cannot stand the administration of the drug. The prescription given is as follows:

R Salicylate of sodium, gr. xxx to lx;  
Tincture of opium, gtt. xx;  
Distilled water, ℥iv.  
The injection is given preferably at night.

#### THE TREATMENT OF ECZEMA OF THE EAR.

A brief note in the *Journal de Médecine de Paris* for February 4, 1894, gives the following directions: In moist eczema of this region, where the eruption is confluent and behind the ear or in the auricle, it is well to wash the parts with a very weak solution of bichloride of mercury, which should be warm. This should be done three or four times daily. After the parts are thoroughly disinfected, they may be dressed by an application of iodol, the auditory canal being closed by a pledget of absorbent cotton. This treatment is very useful in those cases where a discharge from the middle ear has produced irritation. In dry eczema in this region we may also use the mild bichloride wash, and follow it by an ointment composed of,—

R Iodol, gr. xv;  
Lanolin, ℥i.

If the disease involves the external auditory canal, the desquamating epithelium should be

removed by some absorbent wool twisted upon an applicator, and the canal anointed by,—

R Iodol, gr. xv;  
Paraffin oil, ʒi.

The introduction of a tampon of wool will do much towards the keeping of the liquid in the canal. This dressing should be renewed night and morning. Often a cure results in a very few days.

#### WATER IN THE TREATMENT OF SCARLET FEVER.

DR. JOHN H. CARSLAW, of Glasgow, contributes an article "On the Severer Forms of Scarlet Fever, with Special Reference to Antipyretic Methods of Treatment" to the February number of the *Glasgow Medical Journal*.

"With regard to the external use of applications of cold and tepid water," he says, "I hope to have shown,—

"1. That in the large majority of cases they are not required.

"2. That even in simple cases and in anginous cases tepid spongings are useful in allaying restlessness and giving comfort; if the rash has not developed, the addition of mustard being an advantage.

"3. That mustard spongings are particularly useful during the earlier stages of an attack in which nervous phenomena are prominent.

"4. That for the hyperpyrexia of such (nervous) attacks, especially if the rash has developed, repeated cold wet packing is a convenient and efficacious method of treatment, general improvement often following its use.

"5. That local applications to the head may sometimes be of assistance.

"6. That in all cold applications there is need for the exercise of the greatest care."—*New York Medical Journal*, March 10, 1894.

#### ANTIPYRIN AS A LOCAL ANÆSTHETIC IN DISEASES OF THE NOSE AND THROAT.

In the *Gazeta Lekarska*, No. 41, 1893, p. 1067, DR. WROBLEWSKI, physician to the Szpital Ewangelicki, in Warsaw, draws attention to the excellent services obtained from antipyrin when applied locally in cases of painful affection of the nose, pharynx, and larynx, as well as in those of operations upon the organs. In the beginning of his experience with regard to the drug as a local anæsthetic, he used to paint the parts either with a strong aqueous solution of antipyrin or with

the following combination, which proved to be more efficacious:

R Antipyrini, mxxx;  
Cocaini muriatici, ʒi;  
Aque destillatæ, ʒiiss. M.

Later on, however, the writer arrived at the conclusion that parenchymatous injections of a fifty-per-cent. solution of pure antipyrin constituted a by far superior means for securing either therapeutical or surgical anæsthesia. At present, in surgical cases—such as tonsillotomy, excision of the lingual tonsil, galvano-cauterization of granulations on the posterior pharyngeal wall, curetting of the larynx for tuberculous lesions, etc.—he first paints the operation field with a ten-per-cent. solution of cocaine and then injects the antipyrin solution at two points, the total dose introduced at a sitting equalling from 3 to 6 grains (of the drug in substance). Invariably a complete local anæsthesia ensues in from ten to fifteen minutes, which lasts from eight to twelve hours.

Having practised the method in several scores of cases, Dr. Wroblewski did not meet a single instance of toxic or any unpleasant accessory effects from antipyrin, which circumstance he is inclined to attribute to his being cautious with regard to the dosage. Still, in view of certain untoward clinical facts published by other observers, he advises a special cautiousness when using the substance in children and the phthisical, and even to avoid antipyrin altogether in patients suffering from typhoid fever, cardiac or renal disease, arteriosclerosis, etc.—*Provincial Medical Journal*, March, 1894.

#### A PRESCRIPTION FOR DIABETES.

The *Journal de Médecine de Paris* for February 4, 1894, recommends the following:

R Nitrate of pilocarpine, gr. iii;  
Dilute alcohol, ʒi;  
Distilled water, ʒss.

4 or 5 drops of this mixture may be placed upon the tongue two or three times a day.

#### PILOCARPINE IN EAR-DISEASES.

At the recent Fifth General Meeting of Russian Physicians, DR. M. S. JIRMUNSKY, of St. Petersburg (*Vratch*, No. 3, 1894, p. 83), described his experience of the treatment of middle-ear- and labyrinth-affections by injections of pilocarpine. In twenty-seven cases of so-called dry catarrh of the middle ear, in two of

which the drug was injected under the skin and in twenty-five directly into the tympanic cavity, the therapeutic effects were practically *nil*. Similarly, no benefit whatever could be noticed in four cases of inveterate dry catarrh of the cavity with consecutive chronic labyrinthitis. On the other hand, in two recent cases of labyrinthine lesions the remedy proved of eminent service. One of them was that of a peasant lad of nineteen, who, immediately after a fall from a ladder, was brought to the hospital in an unconscious state and bleeding from the left ear. When examined on the thirteenth day, the patient (who had recovered his senses in about two hours after the accident) was found to be absolutely deaf on the left side, both the aerial and bone conductivity being totally destroyed (except the mastoid apex, on which area watch could be faintly heard). Traumatic labyrinthitis with extravasation into the tympanic cavity was diagnosed, and hypodermic injections of pilocarpine commenced without delay. The drug was injected once daily for nineteen consecutive days, beginning with  $\frac{1}{160}$  grain, and increasing the dose  $\frac{1}{160}$  grain every day until  $\frac{1}{8}$  grain was reached. From the sixth day air insufflations through a Eustachian catheter were added; besides, from 4 to 10 drops of a two-per-cent. solution of iodide of potassium were introduced into the tympanic cavity every other day. A steady and rapid improvement set in after the fifth pilocarpine injection. On examination after the nineteenth and last, the lad was found to distinctly hear watch both on the mastoid and auricle, whisper at the distance of 1.5 metres, and ordinary or conversational voice at three metres. The other case refers to a gentleman aged twenty-four, who had contracted syphilis in May, 1892, and undergone the usual treatment in due time. On November 15, 1893, he sought the author's advice on account of deafness, which had suddenly developed about two months previously. The examination elicited the following condition: In the left ear watch hearing = 0; whisper heard at ten centimetres, ordinary voice at 1.5 metres. In the right ear watch hearing normal; whisper at five centimetres, ordinary voice at one metre. Syphilitic labyrinthitis was diagnosed, and subcutaneous injections of pilocarpine in gradually ascending doses (from  $\frac{1}{160}$  to  $\frac{1}{8}$  grain) resorted to. After the tenth *séance* amelioration became marked. After the twenty-fourth the condition was as follows: Whisper, right ear = one metre; left = 1.5 metres; ordinary voice, right ear = four metres; left = four metres. The author feels justified in

laying down the following general propositions:

1. In recent cases of labyrinthine disease of any causation, subcutaneous injections of pilocarpine do actually produce beneficial effects. The earlier the treatment is commenced the better are the results secured.

2. As to inveterate labyrinthine lesions and dry catarrhs of the tympanic cavity, the injections—hypodermic and intratympanic alike—utterly fail to exercise any influence on the course of the disease.

During a discussion, DR. M. I. GORDON, of St. Petersburg, pointed out that he succeeded in obtaining good results from pilocarpine in several cases of dry catarrh of the middle ear in which the treatment had been commenced before a profound deterioration of the patient's hearing power.

PROFESSOR MIKHAIL M. LOMIKOVSKY, of Kharkov, observed that in his hands pilocarpine proved useless in cases of syphilitic deafness.—*Provincial Medical Journal*, March 1, 1894.

#### THE PRESENT POSITION OF THE CREOSOTE THERAPY OF TUBERCULOSIS.

DR. JULIUS WEISS (*Centralblatt für die Gesamte Therapie*, March, 1894) reviews this subject from the discovery of the antiseptic properties of creosote by P. Guttman, in 1887. In Professor Drasche's wards in the Vienna General Hospital he has had abundant opportunities to study the effects of creosote in tuberculosis. He maintains that creosote does not exercise a direct influence upon the tuberculous process. If such an influence existed, then injections into a tuberculous focus and inunctions would do most good. But the contrary is the fact, and its internal employment survives. Stoerk would discard its use altogether, believing that the lessened capacity of assimilation of phthisical patients is still further lowered by creosote. Weiss, however, says that in most cases during creosote treatment an increase in weight, lessening of cough, and improvement of appetite are observed. The last mentioned is the most striking change. Patients are often extremely hungry. This observation applies not only to patients with slight disease at the apex of the lung, but also to advanced cases with extensive infiltration. In a few cases it fails to act as a stomachic. The method of administration needs to be varied to suit the patient. If pill or capsules are not borne, try Hopman's mixture,—

Creosoti,  $\mathfrak{m}_{xlv}$ ;

Tinct. gentianæ,  $\mathfrak{m}_{cv}$ ;

or the formula of Bouchardat (with gentian and Malaga wine), or that of Van der Vloet, with nux vomica.

When creosote is not borne, carbonate of creosote, in proportionately larger dose, should have a trial. Weiss employs it in capsules. He does not think creosote favors hæmoptysis when too extensively used.

His conclusion is that creosote is not a direct specific against tuberculosis, but that it influences the process indirectly by lessening secretion and acting as a stomachic. It is the best remedy for the symptomatic treatment of phthisis which we possess at present.

#### *A CLINICAL, BACTERIOLOGICAL, AND THERAPEUTIC STUDY OF OCULAR DIPHTHERIA.*

GILBERT SOURDILLE, in concluding a work in the laboratory of Panas upon the subject stated in the title, comes to the following conclusions in regard to treatment: Although the therapeutic measures have been diverse, it is universally conceded that in diphtheritic conjunctivitis cauterization with nitrate of silver must be absolutely rejected. He believes, also, that in cases of croupal conjunctivitis in mild form nitrate of silver should not be used. He discards bloodletting,\* mercurial friction, and the internal administration of calomel, which he believes to be harmless in a patient already anæmic from infection. Fieuzal has rendered a real service in reviving an old remedy,—namely, lemon-juice,—which, although successful in some cases, has many failures to its credit. Sourdille recommends this drug, with the reservation that too much confidence must not be placed in it. Almost every antiseptic has been tried,—boracic acid, salicylic acid, phenic acid, sublimate, biniodide of mercury and salicylate of mercury, as well as the yellow oxide of mercury. It seems that such remedies should exercise a favorable influence upon a distinctly microbic disease, and yet they often have failed to produce good effects. Believing from bacteriological investigation that phenic acid in some way fulfils the indications most accurately, but that in previous times it has been used in too strong a lotion, the author recommends the following: Glycerin, 20 grammes; phenic acid, 2 grammes. He proceeds as follows: Reverse the eyelid and wash the conjunctiva with a jet of biniodide of mercury (1 to 20,000). Remove the false membrane wherever possible, and where this is not

possible, rub it with an alkaline solution,—borax or biborate of sodium. Then, with a wad of cotton dipped in the phenic and glycerin solution, rub hard all the diseased points, avoiding as much as possible contact with the cornea. This should be done twice a day. In the interval he applies every two hours a salve of methyl-blue (1 to 1000), basing his preference for this drug on Stilling's original investigations and those recently performed by Janicke, who has demonstrated that Loeffler's bacillus does not grow in bouillon containing methyl-blue in the proportion of 1 to 5,000,000, nor in serum added to 1 to 150,000 of methyl-blue. He has likewise proved that the aqueous solution of methyl-blue (1 to 2000) kills the bacillus in ten minutes and a solution of 1 to 1000 in one minute. In case of corneal complications he treats the ulcer as an ordinary infectious ulcer, cleaning its base with a jet of the antiseptic solution, touching it with the phenated glycerin, followed by an application of pilocarpine and of methyl-blue, and finally dusting in iodoform. He reports six cases thus treated in which he had a good result. Although leucoma of the cornea followed, there were no perforations. He considers his treatment superior to any that has been previously recommended.

#### *PSEUDO-MEMBRANOUS CONJUNCTIVITIS.*

CHEVALLEREAU (abstract in the *Revue Internationale de Bibliographie*, No. 1, January, 1894) reports the following interesting case: Four persons in the same family, living in a narrow street opposite to a house in which three children had diphtheria, developed almost at the same time symptoms of simple croupous conjunctivitis,—namely, a conjunctivitis characterized by slight catarrh, supple eyelids, on the under surface of which there was a false yellowish-gray membrane, easily removable in one piece, the subjacent mucous tissue being uninfiltated. In one case the cornea was ulcerated, but healed rapidly. The treatment consisted in irrigation of the eyelids with a solution of cyanuret of mercury (1 to 1500), compresses soaked in the same solution, and the application of a salve of the yellow oxide of mercury (1 to 50). No sign of diphtheritic poisoning appeared, although there appeared to be a connection between the two slight epidemics,—diphtheria in the one house and croupous conjunctivitis in the other. Only one eye was affected.

### THE DANGERS OF SUBLIMATE SOLUTION IN CATARACT EXTRACTION.

DR. T. E. MURRELL (*Medical Mirror*, February, 1894), although satisfied that bichloride of mercury possesses distinct germicidal value, deprecates its use in cataract extraction after the corneal section has been completed, because, in his experience, it induces striped keratitis and prevents closure of the wound. He believes that if the conjunctiva and lachrymal apparatus are healthy, thorough irrigation of the region with boric acid or sterilized physiological salt solution accomplishes satisfactory results, and quotes interesting experiences of his own in which the use of a 1-to-5000 solution of sublimate resulted in striped keratitis and non-closure of the wound for five weeks. Since this experience he has abandoned bichloride solutions after the corneal section has been made.

He doubts the value of bandaging both eyes after cataract extraction and confining the patient to bed in a dark room. As is well known, Dr. Murrell allows his patients very considerable latitude, not confining them to bed for a single day, unless they prefer it. The unoperated eye is not closed longer than one or two days, and sometimes not at all. He thinks the old method of long bandaging and rest in bed induces delirium, hypostatic pneumonia, and general adynamia.

### ADVANCEMENT OF THE RECTI MUSCLES BY THE FOLDING METHOD.

DR. JAMES M. BALL (*Tri-State Medical Journal*, February and March, 1894) recommends a method of advancement which is done as follows: The antagonistic muscle is first tenotomized; an incision is then made through the conjunctiva and subconjunctival tissues over the insertion of the muscle to be advanced. A strabismus-hook is passed under the muscle and held at right angles to it. The muscle is separated posteriorly from the subjacent tissues, thus permitting it to be lifted up by the hook, so as to form a loop. The size of the loop will depend upon the amount of advancement desired. Two needles, each armed with a strong silk thread, are made to pierce the muscle, which is folded upon itself behind the hook. The needles are then passed beneath the conjunctiva and brought out, one above the other, below the cornea. The strabismus-hook is slipped out and the threads are tied. A superficial suture is used to close the conjunctival wound. If there is considerable over-correction the sutures are removed early; if not,

they are allowed to remain from ten to thirty days. He compares this operation with the capsular advancement of De Wecker, from which it differs in that the sutures are passed through the muscle.

### THE TREATMENT OF TRACHOMA.

DR. FLAVEL B. TIFFANY (*Journal of the American Medical Association*, February, 1894) believes that of the ordinary remedies used in this disease, nitrate of silver and sulphate of copper fulfil useful indications, but that the latter remedy should not be used when there is pannus or ulceration. He then prefers the nitrate of silver. In such cases as require the yellow oxide of mercury, he believes that as ordinarily used it is irritating, and hence employs ten grains each of cocaine and the yellow oxide of mercury to the ounce of albolene.

The radical treatment of chronic trachoma consists of expression of the granulations, especially with Knapp's trachoma forceps or by means of a modified brossage. He believes that in obstinate cases of opacity, other treatments having been ineffectual, jequirity infusion may accomplish some good. To make this infusion he takes eight beans, which are ground and then macerated in an ounce of warm water for twenty-four hours. The fluid is drained, put in blue bottles, and kept in a cool place. Of this solution 1 or 2 drops are instilled into the conjunctival cul-de-sac, or, if a more active application is desired, the lids are everted and the solution applied by means of absorbent cotton. In about eight hours the symptoms of at first a catarrhal and afterwards a purulent conjunctivitis appear and a false membrane is developed, which is then treated on the principles suited to such cases, especially by hot water if the reaction is too great. Dr. Tiffany recommends as trustworthy the solution prepared by Parke, Davis & Co. As this is a strong solution, he advises that it be reduced by adding a few drops of it to as many more drops of water before applying.

### PRACTICAL THERAPEUTICS OF PHLYCTENULAR KERATO-CONJUNCTIVITIS.

SCHWEINITZ (*Philadelphia Polyclinic*, March 10, 1894) divides the treatment of phlyctenular kerato-conjunctivitis into,—

1. The local applications, which consist, during the stage of irritation, of warmed mild antiseptic lotions, atropine drops to maintain mydriasis, occasionally eserine, when there is a tendency to pustular formation on the corneal

margin, and frequent bathing with very hot water. Where there is intense photophobia, incision of the ulcerated fissure usually found at the commissural angle is recommended. In the later stages the yellow oxide of mercury or calomel, provided the patient is not taking iodide of potassium, is regarded as better than iodoform or dermatol, although both iodoform and aristol have given him good results.

2. The constitutional treatment, including proper climate, judicious diet, Lugol's solution, syrup of the iodide of iron, occasionally cod-liver oil, and small doses of the bichloride or biniodide of mercury.

3. The treatment of the naso-pharynx, which is considered of the utmost importance, especially if there is subacute or acute catarrhal inflammation and adenoid vegetations. These are regarded not merely as associated conditions, but as bearing a distinct causative relation to the disease, and often determining the relapses which are so characteristic of the affection.

#### THE ACTION OF ELECTRIC CURRENTS ON THE DISEASED EYE.

VELHAGEN (abstract in the *Revue Internationale de Bibliographie*, No. 1, January, 1894) operated first on the healthy eye by applying one pole to the closed eye and the other to the nape of the neck, and determined exactly the intensity of current necessary to excite a luminous sensation. Children from ten to fifteen years old saw the first flash with a current of from one-twentieth to one-thirteenth milliampère, while for adults a current of one-thirteenth to one-eighth milliampère is required. The arrangement of the electrodes has no effect. Eyes affected by recent or healed lesions of the cornea, or by troubles with the crystalline lens, without complication, behave like normal eyes. In ten cases of serious affection of the retina, no modification, either quantitative or qualitative, of the luminous sensation was observable, which proves, at least, that the retina plays only a very slight part in its production. On the contrary, the electric reaction was changed in six cases of atrophy of the optic nerve. The flash appeared later in relatively slighter forms, but the decrease of the reaction did not proceed parallel with the progress of the atrophy. As soon as the eye perceives the light, the current ought not to exceed three-fourths of a milliampère to produce the reaction. Other cases treated were simple glaucoma, chronic choroidoretinitis, disseminated choroiditis, and pigmentary retinitis. The author concludes that diminution of the electric sensibility of the eye

indicates a change in the optic nerve, and this may be used as a test to determine such changes in cases not settled by ophthalmoscopic examination, or in which this cannot be made.

#### CLEANSING THE HANDS FOR SURGICAL OPERATIONS.

BLAGOWESCHTSCHENSKI (*St. Petersburger Med. Woch.*, No. 4, 1894) thus describes his method of cleansing the hands for surgical operations. They are scrubbed for six or eight minutes in a mixture of 2 parts carbolic acid, 5 parts green soap, and 93 parts boiled water; then for three minutes are thoroughly rinsed in boiled water.

#### BLISTERS OF THE FEET.

In the German army the following application is employed for the rapid cure of blisters of the feet incident to long marches:

R Black soap, 52 parts;  
Water, 27 parts;  
Vaseline, 15 parts;  
Oxide of zinc, 6 parts;  
Essence of lavender, enough to perfume.

—*Bull. Génér. de Thérapeutique*, 2 livre, 1894.

#### ANTIPYRIN AS A LOCAL ANÆSTHETIC IN URETHRAL INJECTIONS.

WALTHIER (*Bull. Génér. de Thér.*, 2 liv., 1894) holds that by means of antipyrin injections of the ordinary antiseptics may be rendered quite painless. His formula is as follows:

R Bichloride of mercury, .02 parts;  
Antipyrin, 2 parts; •  
Distilled water, 200 parts.

Antipyrin is also commended in conjunction with bromide of potassium as being extremely valuable in subduing painful erections. It is given in doses of 15 grains combined with three times this quantity of bromide.

#### TREATMENT OF GONORRHOEAL ORCHITIS.

BETANCES (*La Tribune Médicale*, No. 7, 1894) thus summarizes the ordinary hospital treatment of gonorrhoeal orchitis. In accordance with Fournier's directions, rest in bed, immobilization of the inflamed part, local emollient applications, general baths repeated every day for three or four days and then every second day. Internally, the administration of diuretics,

laxatives, and light nourishment. The patient is kept in the recumbent posture until the entire disappearance of inflammatory phenomena.

HUMBERT orders absolute rest in bed, elevation of the scrotum, general bath once a week, oatmeal poultices, and counter-irritant ointment.

MAURIAC orders a bath three times a week, absolute repose, and purgation every second day, procured by means of Seidlitz water.

DU CASTEL orders rest in bed, application of twelve leeches to the cord, oatmeal poultices, general bath every second day, and on the days when the bath is not taken administration of Seidlitz water.

BALZER orders absolute rest and the application of compresses soaked in lead-water.

---

*THE TREATMENT OF INNOMINATE  
ANEURISM BY SIMULTANEOUS  
LIGATURE OF THE CAROTID  
AND SUBCLAVIAN  
ARTERIES.*

GUINARD (*Bull. Génér. de Thér.*, 6 livre, 1894) states that distal ligature of branches beyond the sac gives the best result in treatment of innominate aneurism. This method is the only one which has given real success, not only for innominate aneurism, but also for aneurism of the arch of the aorta. The exact seat of the dilatation is of no particular importance in deciding for operation, since, whether this be in the aorta, the innominate, or at the origin of the carotid and subclavian, the treatment is the same.

POIVET, of fifty-five cases in which this operation was performed, noted six cures and twenty-two improvements.

WALTHIER tabulated only the cases performed since 1882 under antiseptic precautions. Out of twelve there were ten cures. Even the two unsuccessful cases were relatively satisfactory, since in one the tumor continued to develop slowly and in the other death did not follow until a year after operation, from left hemiplegia consecutive to ligation.

---

*TREATMENT OF FRACTURES.*

SEREIN (*Centralblatt f. Chir.*, No. 8, 1894) described twenty-four cases of fracture treated by massage, and claims for this method cure in an extraordinarily short time. In addition to rubbing, he administered three times daily a powder made up of 2 grains of pyrophosphate of iron, and  $\frac{1}{2}$  grain of phosphate of calcium,

and illustrates by reports of cases the fact that crepitus disappears in eight to ten days and fixation results in less than three weeks.

---

*TREATMENT OF SYPHILITIC NEURALGIA.*

OBELINSKY (*Berlin. Klin. Woch.*, February, 1894) reports the case of a man who had primary and secondary syphilis twenty years before coming under treatment, and for several years had suffered from violent neuralgia, which disturbed his sleep and entirely undermined his health. This pain took the form of intercostal neuralgia, was constant, but only reached an agonizing intensity during the night. He was subjected to the most careful treatment for several years, and travelled from place to place trying baths, electricity, and all the known methods of relief without avail. Even the actual cautery was applied and was as unsuccessful as the other means of treatment. Basing his opinion upon the nocturnal exacerbations and upon the futility of ordinary treatment, Obelinsky instituted a course of hypodermic injections of calomel. After the second the pain grew less in intensity and after the eleventh ceased entirely.

---

*THE PRACTICAL VALUE OF BACTERIOLOGICAL EXAMINATION OF THE  
BLOOD IN CASES OF SEPTIC  
INFECTION.*

CANON (*Berlin. Klin. Woch.*, No. 9, 1894) has made a bacteriological examination of the blood in about seventy cases of septic infection. The blood was usually taken from a vein in the arm. It was inoculated upon agar and control experiments were performed with the pus of the wound. He groups the cases as follows:

1. Pure sepsis,—i.e., bacteria in the blood, but no metastases.
2. Bacteria in the blood, plus metastases.
3. No bacteria in the blood, but metastases,—i.e., pure pyæmia.

The bacteria found were mostly streptococci. In some cases the bacterium coli commune and the pneumococcus were found. Of seven cases of pure pyæmia, four died and three recovered. Search of the blood of the dead body was as unsuccessful as was that of the living in demonstrating the presence of germs. Metastatic abscesses were all due to streptococci. The cases run a somewhat prolonged course. As to the practical bearing of this research, the author holds that these examinations are of little therapeutic value, excepting that sometimes they are of service in determining whether or not

amputation should be undertaken with the idea of cutting off the source of septic poisoning. If living micro-organisms are found in the blood, it is safe to conclude that the time for amputation is past, since only as a rare exception does such a patient recover; yet two such recoveries are reported.

#### ALUMNOL.

SANDER (*Berlin. Klin. Woch.*, No. 12, 1894), after a somewhat extended experience of alumnol in the treatment of gonorrhœa, announces that this agent can in no manner be regarded as a specific. In acute cases it acted no better than other agents commonly employed. In chronic cases its action was very like that of nitrate of silver. This result is interesting in view of the glowing reports presented by Heinze and Liebrecht, who hold that alumnol exerts its astringent action not only on the surface, but in the deeper cellular tissues. These authors report that its action is almost specific in gonorrhœal endometritis, and use it in one-and-a-half-per-cent. watery solution twice daily.

#### TREATMENT OF ULCERS OF THE FOOT.

WITTHAUER (*Archiv f. Dermatologie u. Syphilis*, Bd. xxvi., Heft 3) enthusiastically commends the soziodolate of mercury in the treatment of ulcers of the foot or leg. The application is as follows: After thorough cleansing with soap and water, a plaster is applied made up as follows:

R Soziodolate of mercury, 1 part;  
Lanolin, 90 parts;  
Olive oil, 10 parts.

This is spread on lint and the foot and leg enveloped in it, a pressure bandage being applied. At first this dressing is changed every day, later every fourth or fifth day. Chronic granulations promptly become normal in appearance and cicatrization progresses rapidly. When there is a tendency for certain raw areas to remain sluggish, these are scraped and the fresh wound is sprinkled with a powder made up of,—

R Soziodolate of mercury, 1 part;  
Talc, 9 parts.

Beneath the scab thus formed cicatrization rapidly takes place. The same proportion of the mercuric salt is also commended in the treatment of eczema, the powder made up as just described, or the soziodolate of zinc, 1 part, talc, 9 parts, being used. Both subjective

and inflammatory symptoms are said to disappear rapidly. Sometimes the applications cause burning pain; this is slight and transitory.

#### GALLINOL.

Gallinol (*Journal of Cutaneous and Genito-Urinary Diseases*, vol. xii., No. 138) has, according to CAZENEUVE and ROLLER, an active reducing action on the skin, antiseptic and microbicidal, but not toxic, like pyrogallol acid. In eczema it quiets itching, stops exudation, and causes rapid drying of the surface. It is useful in psoriasis of moderate intensity, especially of the scalp and exposed portions, but not in the old and rebellious cases; in these chrysophanic acid acts better. Administered by the stomach or injected it has little toxic quality, though when introduced into the blood-current it kills by its reducing action. It is an excellent microbicide, especially serviceable in favus, trichophytosis, and other maladies produced by vegetable parasites.

#### TREATMENT OF THROMBOTIC PILES.

BOLTON STERNS (*Therapeutische Monatshefte*, February, 1894) holds that Fowler's solution causes rapid diminution in the size of thrombotic piles, and finally produces a cure. Sulphur is a still more powerful medicament, not only because of its laxative effect, but from its constitutional influence. The preparation administered was made up of a 1 to 3000 solution of sulphide of potassium. Of this, a teaspoonful was placed in a glass of water, and the latter was taken during the course of the day.

#### THE METHOD OF TREATING STRUMOUS DISEASES OF THE EXTREMITIES BY PASSIVE CONGESTION.

At the meeting of the Medico-Chirurgical Society of Edinburgh, December 6, 1893 (*Edinburgh Medical Journal*, No. 464, 1894), MILLER presented some interesting observations in regard to Bier's congestion treatment of tubercular affections of the extremities. This treatment is very simple. It consists in placing a broad elastic band around the affected limb, a few inches above the diseased part, firm enough to produce venous congestion. This congestion Bier believes should be kept up continuously, and the patients should be encouraged to use the limb. The elastic band should be broad, and a layer of lint or wool should be placed under it to protect the

skin. The point of application should also be changed every day or two to prevent abrasion. The distal portion of the limb is supported by a common roller-bandage carried up to the affected part, so that the congested area is limited to the immediate neighborhood of the disease.

Miller gives as an example of this treatment a case of disease of the elbow-joint. The hand and forearm were bandaged; then the elastic was applied to the middle or lower third of the upper arm, firm enough to produce congestive discoloration in the neighborhood of the elbow. Congestion is what is wanted, not œdema, still less anæmia. Pain is always absent, and the patient soon becomes accustomed to any slight discomfort produced.

Bier states that in upward of twenty cases treated at Kiel by this method, the improvement obtained in the majority of cases was very rapid and striking, and in no case did a change for the worse occur. The principle of this treatment was suggested to the author by the old belief that "a congested lung possesses an immunity against tuberculosis."

Miller advises the employment of this measure in strumous joint-disease and skin-affections of the extremities as the result of personal experience. It certainly does no harm; it can be combined with immobilization, and aids its action. It is very inexpensive and easily applied. He does not think that this new method can take the place of amputation, excision, incision with scraping, or of immobilization; nor is it appropriate for hospital cases, because so much time is required in order to carry it out properly. He believes the method warranted in tubercular skin-affections of the extremities; early tubercular disease of joints (combined with immobilization or blisters), especially those in which time is of no great importance; instances of multiple tubercular disease in which more radical treatment is inappropriate.

As an illustration of the last class the following case is reported: B. C., aged twenty-five, admitted December 12, 1892, suffering from tubercular disease of the left ankle, right elbow, little finger of right hand, and right patella. The left foot and the little finger were amputated, while the elbow and patellar disease were treated by Bier's method, with the addition of a splint in each case. After three months the patient left the hospital with the elbow much the same, while the disease of the patella had quite disappeared. At the date of this report the elbow is still much the same, the knee well.

#### *SOME RESULTS FROM THE ADMINISTRATION OF ORGANIC EXTRACTS.*

Some interesting facts are presented by FELKIN (*Edinburgh Medical Journal*, No. 464, 1894) in relation to organic extracts, which, though not affording definite information as to the permanent utility of these remedies, certainly warrant further experiment.

The author employed internal medication. Commencing with 10 minims of the fluid extract, he rapidly increased the dose to a drachm two or three times a day. Occasionally sharp diarrhoea followed the larger doses, and the patients varied in respect to the time when it was advisable to use the extract. Some took it well on an empty stomach, but in others it induced slight nausea, and had to be administered during a meal. This objection was not present in administering tabloids. In a few a rectal injection of the extract at bedtime, after the bowel had been cleansed by a simple enema, was most useful. In others the extract was employed in the form of suppositories or capsules; the latter can be easily introduced, and have the advantage of being readily filled by the patient with the necessary dose. The orchitic extract was invariably administered in this way. Felkin believes that organs such as the ovaries and the testicles possess the power of elaborating an internal secretion, which is perhaps not absolutely necessary, but is of importance to the organism.

The first case in which he administered cerebral extract was that of a boy, aged eight, suffering from pseudo-hypertrophic paralysis. Treatment began February 21. At that time he could hardly crawl up-stairs. The extract was administered regularly until July 24, when he was much brighter, could walk up- and down-stairs easily, took food better, could walk a mile and a half with comparative ease, his muscles were far firmer than at the commencement of treatment, and there was marked diminution in the size of his calves and buttocks. It was very noticeable with how much greater ease he managed to rise from the floor. At this time he passed from the writer's observation until October 2, during which time medicine was intermitted. He had distinctly fallen back.

The next case was one of nervous exhaustion and irritability of temper. Mrs. W., aged forty-five, married; suffered for two or three years from loss of memory, pain in her legs, and inability to walk far without extreme fatigue; nervous and hypersensitive, pale, decidedly anæmic. She commenced brain extract on April 5, half a drachm daily, and continued

this until July 25. At this time she was better in every way. Could walk five or six miles with ease, looked brighter, took three good meals a day, and said she felt a different creature. Since this time she has taken only two doses of brain extract a week, and is going on satisfactorily.

Mr. D. began taking drachm doses of cerebral extract on September 20, after a long bout of drinking. The good effect has been very marked. His abstention from alcohol aided in his improvement, but yet his appetite improved almost at once; he sleeps eight hours at night, gains strength rapidly, and the change in appearance is most satisfactory. Although he previously suffered for months from attacks of diarrhoea, his bowels are now quite regular. Even when on the verge of an attack of delirium tremens he took a complete turn for the better after a week's treatment.

The writer has used the brain extract in three cases of epilepsy with marked success.

In addition he has employed brain extract and tabloids with success in three cases of inveterate insomnia, in two of severe debility and general want of nerve-power, and in four cases of general neurasthenia.

The employment of orchitic extract is strongly urged in cases in which the ovaries have been removed in the hope of quieting hysteria or other nervous conditions. He employed this extract successfully in a case of grave hysteria, and in another of mental instability and nymphomania. In both cases orchitic suppositories were employed. In the case of a delicate, anæmic, highly excitable girl, aged seventeen, commencing puberty, in whom the onset of the menstrual function was accompanied by intense excitability and loss of self-control, cerebral extract acted very beneficially. Two other cases are reported in whom, after removal of the ovaries, severe melancholia, change of voice, and other unfortunate results followed, and on whom the cerebral extract had a markedly beneficial effect.

#### GASTROSTOMY AFTER WITZEL'S METHOD.

CAIRD (*Edinburgh Medical Journal*, No. 464, 1894) summarizes Witzel's method of gastrostomy as follows: The patient is anæsthetized and the customary antiseptic precautions are observed. The usual incision is made, the rectus split along the course of the fibres, and its sheath and the peritoneum are opened. The stomach is then sought for, seized by the fingers, and a portion of the anterior wall as

large as the palm of the hand is pulled out through the wound and packed around with sterilized gauze, moist and warm. The surgeon next opens the stomach. He selects a spot near the lesser curvature, free from vessels, and makes a small incision about a quarter of an inch in length. He has in readiness about two feet of red rubber tubing, in diameter equal to that of a drawing-pencil, and slips about one inch of this into the stomach through the incision, which it accurately plugs. Should there be any excessive bleeding, it may be arrested by a catgut suture, which serves to fix the tube provisionally. Care must be taken to wipe up any escaped fluid from the stomach. The tube, which hangs across towards the greater curvature, has now to be secured in position and a species of artificial œsophagus formed. This is managed by the surgeon raising a fold of stomach on each side of the rubber tube with a series of interrupted silk Lembert sutures, on tightening which the tube is buried for about two inches of its length in the folds. Two or three similar sutures beyond the sunken extremity of the tube effectually shut off the new œsophagus from the peritoneal cavity at the farther end. A little sterilized iodoform powder is rubbed over the stitches, and a second line of sutures are put in over the first to promote the efficient union of the serous surfaces enclosing the tube. Before returning the stomach, a few loose sutures may be passed through the folds and outer portion of its wall at the free extremity of the rubber tube, and on replacing the stomach these loose sutures are secured to the abdominal wall. A funnel is then attached to the rubber tube and as much food as necessary administered. The operation may be completed within thirty minutes.

The patient speedily learns to feed himself; regurgitation of food through the wound is not possible, since the tortuosity of the new channel and the valve-like action brought about by the contraction of the stomach entirely preclude this. The tube should be removed about once a month. The free surplus of the old tube should be cut and a long eyed-probe passed into the stomach through the portion that remains, which may now be removed. The new tube should be strung on a silken thread, the end of which is now to be attached to the probe, and so one readily slides the new tube over the probe onward into the stomach, and, pulling on the silk, thereafter withdraws the probe. Should the œsophagus again regain its function, as in cicatricial stricture, on withdrawal of the tube there is never

any outflow of fluid and the fistula rapidly heals. Autopsy in cases examined several months after operation showed that the new canal gradually shortens, straightens, and its walls become thicker. The inner extremity is found guarded by a funnel-shaped arrangement of concentric folds of mucous membrane, or it projects inward something like the ileo-cæcal valve or entrance of the ureters, thus presenting an efficient valvular defence against escape of stomach contents.

TREATMENT OF PERITONITIS IN WOMEN.

Aside from the etiology of the affection, it is held by LUTAUD (*Revue Obstetricale et Gynécologique*, February, 1894) that general rules regarding the early treatment of peritonitis are practically the same. Two indications are of paramount importance,—first, to control the pain and prevent extension of inflammation; second, to control vomiting, tympany, constipation, and the other secondary symptoms. As to the first indication in the early stages, and especially when the disease is still local, fifteen to twenty leeches should be applied over the painful area. This should be followed by an application over the entire abdomen of flexible collodion, which should be renewed every twenty-four hours. Every hour a pill is administered made up as follows:

- R Extract of opium, gr.  $\frac{1}{4}$ ;
- Sulphate of quinine, gr. i;
- Extract of cannabis indica, gr.  $\frac{1}{8}$ .

If the pain is intense, relief should be given by hypodermic injection containing  $\frac{1}{4}$  to  $\frac{1}{2}$  grain of hydrochlorate of morphine. Opiates, however, should be administered by the mouth, if possible. An ice-bag should be applied to the abdomen, or, if the weight of this cannot be supported, hot turpentine stupes. When vomiting prevents the exhibition of quieting remedies by the mouth, suppositories may be given containing opium and belladonna. Sleep is secured by the administration of an enema containing 30 grains of chloral and the yolk of an egg in 6 ounces of water. Vomiting is treated by effervescing waters, cracked ice, frozen champagne, or the following mixture:

- R Fresh lemon-juice, 1 tablespoonful;
- White or red wine, 2 tablespoonfuls.

Just before this mixture is administered there is added bicarbonate of potassium, 1 tablespoonful, the whole being taken during effervescence. Nourishment is given in the form

of cold beef-juice, milk, and Seltzer. Constipation is best combated by means of castor oil, aided by fractional doses of calomel, or, better still, calcined magnesia may be employed. For the subacute or chronic stages the purgative mineral waters are useful. When the stomach resists laxatives, or when the constipation persists, glycerin injections or suppositories may be used. In case these fail, injection of the more powerful enemata may be found serviceable. When the disease becomes subacute, the following ointment should be applied to the abdomen:

- R Mercury ointment, 20 parts;
- Extract of belladonna,
- Iodide of potassium, of each, 2 parts.

Of this, a portion the size of a hazel-nut should be applied to the hypogastric region three times daily and should be covered in by bandage. Lavage and antisepsis of the genital organs should receive careful attention, hot vaginal lavage being particularly useful.

TREATMENT OF SOFT CHANCER.

DUBREUILH (*Journal de Médecine de Bordeaux*, No. 8, 1894) holds that the most successful treatment of soft chancre is by means of iodoform powder, applied three times daily, and preceded by local washings with one-per-cent. carbolic solution as hot as can be borne.

LANELONGUE holds that for ten years he has been content with the application of iodoform powder.

MENEAU applies pyrogallic acid in the form of a twenty-five-per-cent. ointment.

VENOT advises deep cauterization, followed by application of iodoform.

THE TREATMENT OF SUPPURATIVE SYCOSIS.

Under this title, LEISTIKOW (*Monatshefte f. Praktische Dermatologie*, Bd. xiii., No. 5) classes those cases of suppurative inflammation of the hair-follicles from which project short thick hairs. These cases may present themselves in the form of impetigo-like pustules, follicular and perifollicular abscesses, or as deep funicular swellings in which the hair entirely disappears, and which are followed by scarring. The impetigo-like pustules in the cases of suppurative folliculitis and perifolliculitis are treated with a powder made up of 10 parts of carbonate of magnesium, 15 parts of oxide of zinc, and 1 to 2 parts of precipitated sulphur;

or a paste made up of 10 parts of oxide of zinc, 2 parts of talc, and 28 parts of benzoated lard; or, better:

- R Zinc oxide, 6 parts;  
Sulphur, 4 parts;  
Silicon, 2 parts;  
Benzoated lard, 28 parts.

To this last prescription may be added five per cent. carbolic acid or three to five per cent. salicylic acid. To the first prescription three per cent. resorcin may be added or a one per cent. sublimate; or obstinate lesions may be treated with twenty to fifty per cent. of resorcin in alcohol or with concentrated carbolic acid. In case these applications cause irritation, superfatted sulphur or bichloride soap should be employed, together with soothing plasters, preferably made up of zinc and sulphur. Deep syccosis with marked infiltration is treated with mercuric or carbolic plaster mull, or salicyl-creosote plaster mull. In especially obstinate cases, local applications are made of a five-per-cent. ointment of either pyrogallallic acid or chrysarobin.

#### TREATMENT OF BURNS IN CHILDREN.

WERTHEIMER treats burns in children by first thoroughly washing the injured part with lukewarm boric-acid solution. Over this is placed absorbent gauze which has been soaked in lime-water and linseed oil, each 50 parts; thymol, .05 to .10 part. This is placed over the raw surface in the form of broad strips, is covered in with absorbent cotton, and is held in place by a moderately firm gauze bandage. The dressing should be renewed every day. By the end of the second week the following ointment is employed:

- R Bismuth subnitrate, 9 parts;  
Boric acid, 4.5 parts;  
Lanolin, 70 parts;  
Olive oil, 20 parts.

This is applied on absorbent gauze strips as was the first mixture. Internally, stimulants are administered.—*Archiv f. Dermatologie u. Syphilis*, Bd. xxvi. Heft 3.

#### TREATMENT OF ECZEMA.

KLOTZ, in the course of a paper upon the principles of antiseptics in the treatment of eczema, holds that it is well to begin by producing thorough disinfection of the affected surfaces. Thus, after removal of crusts with

water and soap, the part should be washed with corrosive sublimate not stronger than 1 to 3000 or 1 to 5000. This solution is used hereafter morning and night by means of a pad of absorbent cotton, and, if possible, this pad, well soaked in the solution, is to be kept applied to the diseased surfaces from half to one hour during each washing. The parts are then dried, and a ten-per-cent. boric-acid vaseline ointment is rubbed into the skin and covered with a cotton bandage. In a few days all suppuration ceases. In milder cases two- or three-per-cent. boric-acid lotion takes the place of the corrosive sublimate. In acute inflammatory cases, especially when the legs are involved, with or without ulcers, 2 to 4 parts of acetate of lead are added to each 4000 parts of boric-acid solution, and compresses soaked with this mixture are constantly applied for several days. Even in the dry forms of eczema these wet applications are of service.

PETRILLI warmly recommends zinc sulphate as an external application in the treatment of eczema, basing his favorable opinion upon a number of reported cases in the *Archiv für Dermatologie und Syphilis*, Bd. xxvi. Heft 3.

#### TREATMENT OF DEPRESSION OF THE SKULL OF THE NEW-BORN.

JENNINGS (*New York Medical Journal*, vol. xix., No. 10) holds that depressions in the skull of the new-born should not be left to nature, since many cases of hemiplegic epilepsy and impaired intellect result, and the deformity incident to the indentations often persists. He offers the following conclusions to his paper:

Use pneumatic traction. If this fails, trephining is the best operative procedure.

Trephining, *per se*, is not a dangerous operation.

The removed button of bone can be replaced with good prospect of its union, on account of the vascularity of the bones at this age.

Frontal depressions rarely correct themselves.

Immediate action is desirable, if there are symptoms which indicate operation.

If the depression is still exaggerated at the end of two weeks, an operation should be performed to prevent subsequent brain-trouble and overcome the deformity.

#### TREATMENT OF ACUTE PSORIASIS.

In the treatment of acute psoriasis arsenic is to be avoided, but iodides are to be given in large doses, the beneficial effect being due in part to their diuretic influence. Wine of anti-

mony is to be used with great caution. Turpentine, when the kidneys are healthy, is sometimes of service, apparently because of its well-known effect in producing contraction of blood-vessels and thus lessening hyperæmia. In the local treatment a point of cardinal importance is the careful removal of the scabs and the application to all portions of the lesion of an antiparasitic medication. This represents the views of Crocker, as quoted from the *British Medical Journal* by the *Therapeutische Monatshefte* for February, 1894.

#### THE EMERGENCY TREATMENT OF URINARY RETENTION FROM ENLARGED PROSTATE.

REMY (*Bulletin Générale de Thérapeutique*, 65 année, tome cxxvi) holds that when there occurs complete retention with impossibility of passing instruments by the urethra, the suprapubic puncture should be made and a soft catheter introduced through the canula of the instrument employed for tapping. The canula should be taken out and the catheter left in place until the bladder can again be drained through the urethra.

#### A NEW TREATMENT OF ERYSIPELAS.

ARNOZAN (*Archives de Médecine et de Pharmacie Militaires*, No. 2, 1894) strongly recommends the following treatment: Quinine is administered in doses of 8 to 16 grains, in accordance with the temperature, 4-grain pills being given three or four times daily, so that the patient is kept constantly under the influence of the drug. Over the affected surface is applied an ointment made up of,—

R. Bichloride of mercury, gr. i;  
Lanolin,  
Vaseline, of each, ʒss.

Of twenty-five cases thus treated there was frequently noted a prompt arrest of the eruption or, in case this failed, marked alleviation of the symptoms. The temperature fell in three or four days, and the average duration of the attack was five to seven days.

#### EXTERNAL ŒSOPHAGOTOMY FOR THE REMOVAL OF FOREIGN BODIES.

CAHIER (*Archives de Médecine et de Pharmacie Militaires*, No. 2, 1894) reports the case of a sergeant whose false teeth were lodged in the œsophagus in the region of the cricoid cartilage. Measurement showed that the foreign body was eight inches from the incisor teeth.

Attempts at extraction by forceps were futile; therefore external œsophagotomy was performed, the incision passing from the sternal notch to the upper border of the thyroid cartilage to the left of the middle line. The omohyoid was divided and a portion of the sternothyroid. A longitudinal incision was made in the œsophagus, an œsophageal sound was introduced through the wound, and the whole incision was packed with iodoform gauze with the exception of the upper portion, which was sewed. The patient died three days later. Autopsy showed that the œsophagus had been ulcerated through by the foreign body and that the mediastinum had been thus infected. This case shows that immediate operation should be performed for such accidents, especially when the foreign body is irregular. Indeed, Terrier states that a physician should never leave a patient who has a foreign body lodged in the œsophagus without having in one way or another removed the obstacle. Immediate suture of the œsophagus may be practised when the foreign body has been lodged such a short time that ulcerative inflammation has not occurred. Under other circumstances the wound should be packed.

#### TREATMENT OF DYSMENORRŒA.

DR. WHIPPLE (*Buffalo Medical and Surgical Journal*, vol. xxxiii., No. 8), after an interesting and profitable discussion of the subject of dysmenorrhœa, reaches the following conclusions:

The suggestion of a vaginal examination is a great shock to the sensitive, shrinking nature of the young girl, worn out with suffering at each menstrual period, and terrified at the expectancy of a recurring one. Nor will the considerate physician exact this until all probable and improbable remedies have been exhausted, without success, in the endeavor to overcome the persistent dysmenorrhœa. If the sufferer is then unrelieved, more radical measures must be employed.

The first step in the treatment of the married woman should be a thorough examination, for the purpose of detecting any existing displacements, stenosis of the cervical canal, or congestion of the generative organs.

If displacements, flexions, stenoses, occlusions, or polypi be present, and in some diseased conditions of the ovaries, only operative measures will give relief.

In many cases due to inflammation of uterus and ovaries the use of galvanism has given great satisfaction in completely overcoming the existing dysmenorrhœa.

If the patient be anæmic or chlorotic, a tonic course of treatment, with enforcement of strict hygiene, is indicated.

The habit which some young women and girls have formed of using alcohol and morphine, at first for relief from dysmenorrhœa, and finally for every ache and pain, until they find the habit too firmly fixed to be discontinued, should be denounced in no uncertain terms by the family physician.

In those cases characterized by a scanty menstruation, in which no well-defined local or organic lesion can be found, but where a neurotic or hysterical tendency prevails, the employment of drugs generally proves successful; but a proper selection of remedies can be made only after a careful study of each individual case, since that agent which brings relief to one from distressing dysmenorrhœa may be utterly worthless for another, and what proves a success at one time may be a failure at the next.

#### *FISSURE OF THE ANUS AND PAINFUL EROSION OF THE RECTUM IN INFANTS AND CHILDREN.*

KOPLIK (*Mathews's Medical Quarterly*, vol. i., No. 1) recommends the following treatment: Chloroform is administered, and when anæsthesia is complete the Sims speculum is passed into the rectum. The parts first having been cleansed with soap and brush, a full-sized speculum is used, an exploratory view of the lower bowel being thus obtained. If no growth, such as a polypus, be present, the speculum is withdrawn and the anal ring (sphincter) is thoroughly stretched with both thumbs, both in an antero-posterior and transverse direction. The fissure is burnt with a Paquelin cautery in its longitudinal diameter; a tampon of cotton may now be inserted high up, so as to support the bowel. The operation lasts but a few minutes, and there is no after-treatment with opium.

The patient during the operation is placed on the back on a hard table, with a pillow beneath the buttocks; the thighs are held by the assistant up against the abdomen. The tampon is removed after twenty-four hours. The parts are sometimes excoriated from the effects of the above manipulations. In these cases a ten-per-cent. ointment of resorcin is of value, applied twice daily, both for its antiseptic and apparently local anæsthetic effects. In no case of the writer's did the bowel descend through the anal ring after operation. No dosing with opium to restrain the intestinal movements is necessary. The recovery in all cases was complete and lasting. The constipation disap-

peared also with the return of the sphincters to their normal condition.

In relation to the prophylactic treatment, Henoeh advises in cases of constipation in infancy a change of diet from a milk to a mixed diet. This is applicable to older children and infants whose dentition is well under way. In children under a year old other things must be thought of. A mixed diet is only applicable in milder forms of constipation. In these forms we exclude the farinacea and starches and curtail the milk, which in cold weather may be administered in the form of unsterilized cream or cream and milk equal parts. In young children we sterilize the milk in warm weather, according to the author's method of 87° to 90° Celsius.

The writer has found that by far the most useful drug in the treatment of constipation of the ordinary type has been the fluid extract of cascara sagrada. The dose for an infant under six months of age is 10 minims, taken at night in some agreeable elixir or syrup. Older infants may take even as much as 30 minims without ill effects, such as vomiting.

The introduction into the rectum of suppositories of soap, coca-butter, or glycerin as an habitual practice is to be strongly deprecated for the same reason as are habitual injections. The use of suppositories or injections cause excoriation and also eventually fissures. In saying this, the writer is conscious of the fact that the use of the above remedies is sanctioned by some experienced men, but he has only seen harm in allowing the average nurse or mother to thus habitually treat the infant. In one case the author is certain that the hard nozzle of the syringe only aggravated, if it did not cause, the fissure.

The administration of drugs to the nurse or mother in the case of breast-fed infants, in order that the milk may become the vehicle of the drug, has not met with success in the writer's hands. It has only upset the normal functions of both nurse and child.

Certain infants suffer from painful excoriations about the anus in the form of chronic or subacute eczema. In these cases there are any number of minute fissures in the anal folds. This condition, if neglected, may well give rise to serious fissure. In these cases the acidity of the movements seems to be at fault. The infant should have its diet corrected, and, if necessary, have some drug—such as bismuth, which is excellent—in sufficient quantity for a few days to correct the error of intestinal changes. The local eczema or intertrigo is best treated with resorcin ointment, ten per

cent. This is applied to the parts three times daily. As soon as it is applied it is wiped off, leaving the parts simply with a thin coating; they are then dusted with oxide of zinc which has been very finely ground in a mortar to eliminate the gritty particles. The excess of oxide of zinc must be blown off as soon as applied, else it will cake and become an irritant. In this way, carefully applied three times daily, these remedies will soon cause a troublesome anal eczema to disappear.

#### TREATMENT OF VOMITING OF PREGNANCY.

LUTAUD (*Revue Obstetricale et Gynécologique*, February, 1894) states that vomiting of pregnancy is best treated by cocaine. The action of this drug is often strengthened by combining it with antipyrin. Thus, the following prescription:

R Chlorhydrate of cocaine, gr. iss;  
Antipyrin, gr. xvi;  
Distilled water, ℥iv.

Sig.—1 teaspoonful every half-hour until vomiting ceases.

If the stomach will not tolerate this quantity of liquid, 10 drops of a one-and-a-half or two-per-cent. solution of cocaine are administered, repeated at one- or two-hour intervals.

At times the application of cocaine to the os is extremely valuable. The following prescription may be used:

R Hydrochlorate of cocaine, gr. xvi;  
Extract of belladonna, gr. iv;  
Vaseline, ℥ss.

Cotin's method of dilating the os with the finger sometimes causes immediate cessation of vomiting. Occasional success will follow Routh's procedure, which consists in exposing the uterine neck by means of a speculum and painting with tincture of iodine. In cases of moderate severity the following mixture will be found serviceable:

℞ Tincture of iodine, ℥ii;  
Chloroform, ℥ii.

Sig.—5 drops night and morning at meal-times, taken in Seltzer-water.

#### TREATMENT OF VAGINISMUS.

LUTAUD (*Revue Obstetricale et Gynécologique*, February, 1894) recommends copious injections with mild antiseptic, non-irritant lotions, such, for instance, as the following:

R Chlorate of potassium,  
Laudanum, of each, 200 parts;  
Tar-water, 200 parts.  
Tablespoonful to a quart of water.

These injections should be made thoroughly, being carried well into the vagina by means of a glass nozzle. Each evening a vaginal bougie should be introduced, made up as follows:

R Coca-butter, ℥ii;  
Hydrochlorate of cocaine, gr. iv;  
Extract of belladonna, gr. iiss;  
Bromide of strontium, gr. iv.

In case of leucorrhœa a cylindrical suppository is advised, made up of,—

R Coca-butter, ℥ii;  
Iodoform, gr. xv;  
Extract of belladonna, gr. viii.

The vulva and the vaginal introitus are frequently painted with a five-per-cent. solution of cocaine. This is especially to be used immediately before sexual approach. Moreover, the parts should be thoroughly lubricated at this time. Prolonged warm baths are useful combined with dilatation. In certain rebellious cases where surgical operation is not allowed, coitus may be accomplished after the hypodermic administration of a full dose of morphine. As a single approach may cause conception, the suffering may be thus permanently relieved.

#### FIBROID TUMORS OF THE UTERUS.

BURRAGE (*American Journal of Obstetrics*, March, 1894) closes a paper on the subject of fibroid tumors of the uterus with the following conclusions:

Hysterectomy is contraindicated in a majority of cases of fibroids, because of the high rate of mortality and because it unsexes the patient, the latter an important consideration in younger women.

Electricity is the best therapeutic means at our disposal to combat pain, hemorrhage, and impaired health and strength.

Intrauterine galvanism is most serviceable.

We must not look for a permanent reduction in the size of the tumor.

Galvanism—vaginal, intrauterine, or by puncture—does not cause abscesses or adhesions.

Galvanism is of no use as a means of diagnosing the presence of pus.

Treatment by electricity after the Apostoli method is absolutely safe.

Every case of fibroid tumor of the uterus should be under competent medical observation, because of the danger of malignant degeneration, kidney-disease from pressure on the ureters, complications during pregnancy, and the liability of the occurrence of pain and

hemorrhage and functional nervous disorders, especially during a delayed and protracted menopause.

#### TRIFACIAL NEURALGIA.

QUENU (*Universal Medical Journal*, vol. viii., 1894), after alluding to the frequency with which neuralgia recurs after resection of the inferior maxillary nerve, thus describes the operation which he has devised for sectioning this trunk before it passes through the oval foramen. This operation, he states, requires but five minutes in a living subject. The temporal fossa is denuded by a curved incision as far as the crest, separating it from the zygomatic fossa. The zygomatic arch is sawed or cut at its two extremities, and the temporal flap severed and thrown as low down as possible. The skull is opened with the trephine above the crest just mentioned. This opening is then increased towards the lower portions by means of chisel forceps. The dura mater is detached with the finger, while on the external side the vault of the zygomatic fossa is rapidly severed by a rasp. The wound need not be cleansed, since the finger is a sufficient guide. When the forceps is two-fifths of an inch from the crest, the foramen ovale is felt for by means of a small hook, practically a short aneurism needle. The left index finger, inserted transversely, enters a small depression, limited in front by the edge of the pterygoid process, in the back by the sharp spine of the sphenoid. The foramen ovale and the foramen spinosum lie in this region, and the hook introduced flat upon the finger and turned upward engages at once in the oval foramen, since the blunt point of the hook is too large to enter the foramen spinosum. The pterygoid and temporal muscles are pushed back by a large retractor and the nerve is resected as far as the Gasserian ganglion. This operation should be performed under the guidance of the eye. Where this is difficult or impossible, it is stated that if a small curette introduced into the foramen ovale grates upon the osseous substance of the latter, this is a proof that the nerve has been divided.

#### DRAINAGE IN COMBINATION WITH A PERMANENT DRESSING.

KRONACHER (*Wien. Med. Presse*, No. 2, 1894), on the basis of eight years' experience, warmly commends the method of drainage combined with permanent bandage suggested by Sée. This consists in placing an ordinary rubber tube so that the wound is thoroughly drained. Silk thread is attached to this tube and brought

out beneath the dressing. The ends of the thread are secured to the surface outside the wound, dressing with gauze and collodion, and over this is placed a small antiseptic dressing. On the second or fourth day this small dressing is removed, and by means of the threads lying beneath it the tube is drawn out from the wound and from beneath the main dressing; the latter is then re-enforced by some additional turns of a roller.

#### ANTISEPTIC TREATMENT OF BURNS.

NAGOTTE (*Centralblatt f. Chir.*, No. 7, 1894) shows that the most rapid healing and the least deforming scar after a severe burn is to be obtained by surgical antiseptics. To secure this it is necessary in cases of extensive burns to administer an anæsthetic and to subject the wound to thorough, even rough, applications of the methods and solutions ordinarily employed in cleansing infected wounds. Once thoroughly disinfected, an effort should be made to procure healing under dry dressing. As remedies to be employed for maintaining disinfection, iodoform, thyol, ichthyol, and especially subnitrate of bismuth are commended.

#### INTESTINAL ANASTOMOSIS (WITH SENN'S PLATES) FOR CANCEROUS OBSTRUCTIONS.

ELLIOT (*Boston Medical and Surgical Journal*, March 22, 1894) reports the following case treated by this method: The patient was a feeble man, sixty years old. In August he had an attack of vomiting and diarrhoea. In September he began to lose his strength and to have attacks of dizziness. He also had a serious stoppage of the bowels, with pain on the right side, which was relieved by castor oil. He soon found that solid food gave him colic; he therefore took only liquids. In October he had more pain on the right side of the abdomen and the movements became more difficult; then the abdomen began to swell.

In November all his troubles became worse; he ate less, and had more pain. He then entered the Massachusetts General Hospital. There he vomited for four days, ate nothing, and was kept alive by nutrient enemata. He improved somewhat in his general condition, but had absolutely no movements of the bowels. No tumor could be felt.

On December 15 the abdomen was opened, and the bowel was found to be completely obstructed by a cancerous mass in the cæcum. An anastomosis was then made, with Senn's

plates, between the colon and the ileum. The operation did not take more than fifteen or twenty minutes; the patient, feeble as he was, had little or no shock. He made a rapid recovery. His bowels moved in twenty-four hours, and he took solid food on the fourth day.

Three months after operation he has free and natural movements of the bowels and has gained twenty-two pounds. He has no pain and feels perfectly well. The growth has increased in size and can be plainly felt in the abdomen. If he were a stronger man removal would be advisable.

The author considers intestinal anastomosis one of the greatest advances in surgery. The operation is very quickly and easily done. The advantages to the patient of an intestinal anastomosis over an artificial anus are enormous.

---

#### GALLOBROMOL IN THE TREATMENT OF CASES OF ACUTE AND CHRONIC GONORRHOEA.

CAZENEUVE and ROLLET (*Journal de Médecine de Paris*, February 18, 1894) have used gallobromol in the treatment of gonorrhœa. One case of early acute inflammation, the nature of which was determined by microscopic examination, was treated. This was aborted by a ten-per-cent. solution. Cases in which the discharge was well established or had become chronic were treated by copious irrigations—a pint at a time—of one- or two-per-cent. solutions. As a result of this treatment, the pain was gradually relieved, erections became less frequent, the discharge quickly disappeared or, at least, became reduced to a minimum. Chronic cases yield kindly to injections with the ordinary syringe and especially to instillation made in the posterior urethra. For the latter purpose a two-per-cent. solution was used.

---

#### TREATMENT OF GONORRHOËAL ARTHRITIS.

This disease, according to GUPAN (*Gazette Médicale de Paris*, No. 9, 1894), if acute and with slight effusion, calls for the immobilization of the affected joint in the most favorable position for ankylosis. Compression should be made by means of a flannel bandage beneath which is placed cotton. If, after four or five days, there is no relief of symptoms, the syno-

vial cavity should be opened by puncture and should be washed out with a solution of bichloride (1 to 4000). If this gives no relief, arthrotomy should be performed. Where there is abundant articular effusion, puncture and compression is indicated. When the liquid presents a purulent appearance, arthrotomy is indicated. When the arthritis is suppurative, arthrotomy should be performed immediately. This operation is also indicated when the effusion has lasted for several weeks without yielding to gentler means. This operation implies the observance of every antiseptic precaution, and may be performed under the influence of cocaine. The incision into the synovial cavity should be free and should be washed out with mild antiseptic solution. If possible, the whole cavity of the joint should be explored with the finger, and adherent and fibrinous masses should be removed, the articulations drained, the opening sutured, and an antiseptic pressure bandage applied. As soon as the active symptoms have subsided, passive movement is instituted.

---

#### GOOD RESULTS FOLLOWING MODERN ANTISEPTIC TREATMENT IN LITHOTRITIES.

POUSSIN (*Archives Clinique de Bordeaux*, No. 2, 1894) reports two cases of death out of thirty-five lithotrities, a mortality considerably above that of Guyon, who lost but one case out of one hundred and eighty operations. The author calls attention to the marked diminution in mortality which followed the application of modern antiseptics to the operation.

---

#### CHLOROFORM VERSUS ETHER NARCOSIS.

KORTE (*Berlin. Klin. Woch.*, No. 10, 31 Jahr), after freely granting the much greater safety of ether as an anæsthetic from a statistical stand-point, shows, on the basis of several hundred cases he has observed, that chloroform is slightly quicker in producing full anæsthesia. Under ether the pulse was found fuller and stronger than under chloroform. Heart syncope almost never occurs under ether, but under chloroform is frequent, sometimes running to a fatal issue. Breathing under ether is more natural than under chloroform. Stoppage of the throat by dropping backward of the tongue occurs less frequently under ether than under chloroform. Vomiting follows ether less frequently; prolonged excitement lasting en-

tirely through the operation was in a series of contrasted cases more frequently observed under chloroform than under ether. Clonic contraction of the muscles with tetanic rigidity of the limbs was frequently observed in the beginning of etherization. In a few cases it persisted, and was only relieved by administering a few drops of chloroform. As to the kidneys, the author holds that *ether has no bad effect upon them*. Out of the six hundred cases anaesthetized, two hundred and three, either before or after etherization, showed albumin in the urine. In seven cases albumin was present on operation. Its quantity was not influenced by administration of ether. In six cases before operation patients exhibited no albumin, but after operation there was distinct albuminuria. In all of these the presence of albumin could be explained on grounds other than those connected with the administration of ether, although in four cases slight transitory albuminuria was apparently associated with the administration of this drug.

*Bruns has shown that the action of chloroform upon the kidney is far more severe than is that of ether.* The tracheal and bronchial mucous membranes are always somewhat irritated by ether. The author holds that the only contraindications to the use of ether are recent bronchitis, inflammatory diseases of the lungs, or acute obstruction of the larynx or trachea; finally, for operations on the face and mouth, for the completion of which a face-mask or etherizing apparatus must be removed for a long period. With these exceptions, ether is always to be preferred to chloroform.

#### THE PREVENTIVE TREATMENT OF SYPHILIS.

WICKHAM (*Gazette Médicale de Paris*, No. 9, 1894), under the above title, discusses what he considers the best method of preventing any of the manifestations of syphilis after the disease has once been diagnosed. He holds that the first year of treatment should be mercury, the second year mercury, the third mercury and iodide, the fourth iodide, and the fifth iodide.

#### AMPUTATIONS AT THE HIP-JOINT.

ESTES (*International Journal of Surgery*, vol. vii., No. 3) reports seven amputations at the hip-joint. He lays particular stress upon hemorrhage as the cause of fatal shock, and took

every precaution in his operations to avoid this. As a result six cases recovered. His method of procedure is first to force the blood out of the extremity, next to tie the femoral vessels at Poupart's ligaments between two ligatures and divide them; next an anterior flap is gradually made from without inward, great care being taken to secure all known vessels before they are cut by means of double ligatures or two hæmostatic forceps, and all muscular or small branches, when cut, must be immediately secured. After the capsule is reached anteriorly the posterior flap is dissected up with the same care as to securing the blood-vessels. Finally, the capsule is incised and disarticulation is accomplished in the usual way. By this operation, which the author calls the gradual dissection method, not more than an ounce of blood is lost. Estes compares his results with Wyeth's, who has recently tabulated forty cases performed by various operators. In this tabulation there is a general mortality of 22.5 per cent., although nearly all of the operations were done for pathological conditions. Of the eight cases done for injuries, all perished. Three of Estes's cases were railroad crushes, and all recovered. In case of crush, he advises waiting until reaction occurs, thoroughly cleansing the wound in the mean time and checking hemorrhage by pressure.

---

### Reviews.

---

THE UNITED STATES DISPENSATORY. By George B. Wood and Franklin Bache. Seventeenth edition, revised and illustrated. By H. C. Wood, M.D., LL.D., Joseph P. Remington, Phm., F.C.S., and Samuel P. Sadler, Ph.D., F.C.S.  
Philadelphia: J. B. Lippincott Company, 1894.

It is a credit to the professions of medicine and pharmacy, and the American profession in particular, and still more to Philadelphia as a medical and pharmaceutical centre, that so noble a work as the United States Dispensatory should have its birth in this city, and should continue to be so ably edited by the successors of the eminent men who originally compiled it.

For many years it was the only book which could be relied upon by the physician and druggist who desired general information for professional use, and until the advent of the National Dispensatory, the fifth edition of which was reviewed in the last number of the GAZETTE, it held undisputed sway. The names

of Stillé and Maisch, however, are such an earnest of ability as authors and compilers that any work issuing from their pens must be regarded as a powerful rival of similar compilations. The question which is of interest to the average physician and pharmacist is as to which of these two volumes he wishes to purchase, as few persons will desire to be possessed of both of them. As was pointed out in the review of the National Dispensatory, the work of Professor Maisch is unrivalled, while that of Professor Stillé, in considering the therapeutics of the various remedies, is, it goes without saying, equally good. To the physician who desires to obtain a large amount of therapeutic information from his Dispensatory we cannot recommend the United States, since the articles on the medicinal uses of drugs prepared by Dr. Stillé are much more exhaustive and are accompanied by copious references to recent medical literature. Thus, in the article upon "Chloroform," the most recent discussions concerning the action of this drug, at least up to July, 1893, are included, whereas in the United States Dispensatory the very important discussions which have gone on concerning the influence of this drug are almost totally ignored, except in a footnote of five lines on page 376, where reference to some statistics, under date of October 29, 1892, are given, otherwise little change being made between the text of the sixteenth edition and the one now under review. The ability of Professor Remington to describe the art of pharmacy renders his work on the United States Dispensatory most valuable, but this is balanced, on the other hand, by the careful work of Caspari on the National. For the physician we advise the National, for the pharmacist either will be a good purchase.

FOSTER'S ENCYCLOPÆDIC MEDICAL DICTIONARY, BEING A DICTIONARY OF TECHNICAL TERMS USED BY WRITERS ON MEDICINE AND THE COLLATERAL SCIENCES IN THE LATIN, ENGLISH, FRENCH, AND GERMAN LANGUAGES. By Frank P. Foster, M.D. Vol. IV. Illustrated.

New York: D. Appleton & Co., 1894.

At last the final volume of this monument to American learning and industry has been placed before the medical profession by its learned editor and his collaborators, and it will stand for all time as a classic both in the literature of medicine and the collateral sciences. The volume opens with a beautiful plate, showing the normal and abnormal constituents of the human urine. The text of the work extends from Minn to Zyth. The disadvantage which surrounds the use of all small dictionaries is the necessary exclusion of words which are

rarely used and condensations of the definitions which are given. As the name of this book implies, it is encyclopedic not only in its wide scope, but also because it partakes of the nature of an ordinary encyclopædia, in giving full descriptive definitions of nearly all the terms found in its pages. We trust that the work, which has cost so many years of labor and industry, will be appreciated by the profession for which it was prepared. The letter-press and binding are, if possible, even better than in the previous volumes, and are a credit to the publishers of this splendid work.

TRANSACTIONS OF THE MEDICAL ASSOCIATION OF THE STATE OF MISSOURI at its Thirty-Sixth Annual Session, held at Sedalia, Mo., May 17, 1893. Jefferson City, Mo., 1893.

This volume of the Transactions of the Medical Society of Missouri is extremely creditable to the practising physicians of that State. Among the many valuable papers are to be noted a *résumé* of the Progress of Rectal Surgery, by Potter; a General Summary of Animal Parasites, by Ohman-Dumesnil; and Penetrating Gunshot Wounds of the Abdomen, by Marks. In this latter paper there are reported seventeen cases, with a mortality of a little below thirty per cent., though there was an average of five perforating wounds in each case. All of the papers are of an unusually high degree of merit, and combined in book form will doubtless prove a valuable addition to the surgeon's reference library.

THE YEAR-BOOK OF TREATMENT FOR 1894. Philadelphia: Lea Brothers & Co., 1894.

To those members of the medical profession who have not subscribed to the THERAPEUTIC GAZETTE "The Year-Book of Treatment" affords a useful summary of the therapeutic advances which have been made during the year in a much more brief and therefore more incomplete form than can be found in the twelve numbers of the GAZETTE for the same time. Much of the information which is contained in this volume will necessarily seem a number of months old to readers of this journal, and we are pleased to note that the various editors employed in the compilation of "The Year-Book of Treatment" frequently quote the editorial articles and Progress columns of the GAZETTE. The book itself is to be considered a valuable addition to the actively engaged practitioner of medicine. We notice that, by a curious typographical error, *strophanthus* is said by H. C. Wood to act quickly and "pugnaciously" as compared with *digitalis*. We presume that the word fugaciously is intended.

A PRACTICAL TREATISE ON MEDICAL DIAGNOSIS FOR STUDENTS AND PHYSICIANS. By John H. Musser, M.D. Philadelphia: Lea Brothers & Co., 1894.

Those who have known for some time that Dr. Musser was about to publish a book on this subject, and who have also known his skill as a practical physician, have been looking forward to the appearance of this work. We find it is at once a credit to him as an author and a valuable addition to medical literature. Contrary to our expectations, the work is very considerably larger than the average text-book on this subject, numbering nearly nine hundred pages; but notwithstanding its size, in no portion of it can the reviewer point out redundancy or instances where subject-matter might be readily dispensed with. The whole book impresses one as being the concentration of a very thorough knowledge of all the facts resorted to in the making of a careful diagnosis by means of modern methods. If any criticism can be offered, it is that, in the effort to condense, certain paragraphs lack the clearness in expression which is so necessary in a book for students. Notwithstanding this fact, we are confident that Dr. Musser's book will at once take a prominent and permanent position among the text-books of the medical schools of the country, and we recommend it most highly to those practitioners who wish not only to get the views of the general profession in regard to important points of diagnosis, but who also desire a work in which the author expresses his own opinions, based upon careful observation and wide experience.

AN AMERICAN TEXT-BOOK OF THE DISEASES OF CHILDREN. By American teachers. Edited by Louis Starr, M.D., assisted by Thompson S. Westcott, M.D. Philadelphia: W. B. Saunders, 1894.

The disadvantage of works composed of the writings of many individuals is the fact that the articles are necessarily uneven as to quality and as to scope, and this objection increases in importance in direct ratio to the number of contributors. We cannot understand why so many gentlemen should have been asked to write for a book of less than twelve hundred pages, for no less than sixty-three authors contribute to the volume.

One of the most practical articles of the book is that by the editor, Dr. Starr, upon the investigation of disease and the general management of children, which is followed by a valuable article by Dr. E. P. Davis upon injuries incident to birth and the diseases of the new-born.

The article on malaria, by Thayre, of Balti-

more, is particularly interesting from a pathological and etiological point of view, but disappointingly short in the therapeutic consideration of the diseases under discussion. Dr. Blackader's article upon gastric catarrh and gastric ulcer is also worthy of notice, and the general catarrhal state known as mucous disease is well considered by Dr. Edwards.

The article upon hæmaturia, by Dr. Buckingham, of Boston, is, unfortunately, short, a fault which perhaps could not be avoided in so condensed a work.

A special feature of the book which strikes us as we look through it are the full-page color illustrations, which are singularly accurate.

The volume gives evidence of having been most carefully edited, and reflects credit upon the contributors, the editor, and the publisher.

A MANUAL OF THERAPEUTICS. By A. A. Stevens, M.D. Philadelphia: W. B. Saunders, 1894.

The arrangement of this little book is precisely that of a somewhat larger volume which has been in the market for several years. Part I. deals with the physiological action of drugs, Part II. with drugs themselves, Part III. with remedial measures other than drugs, and Part IV. with articles on diseases. As the book only numbers about four hundred and fifty pages and is a small octavo, it has naturally been impossible for the author to give anything else but very concise statements concerning the subjects treated. Thus, the article upon electricity covers scarcely seven pages, and similar abbreviated articles can be found in many places through the book. Nevertheless, the author is to be congratulated upon having presented the medical student with as accurate a quiz manual of therapeutics as it is possible to prepare, although there are a number of errors in this edition which will probably be corrected in the future ones. The list of general anæsthetics—namely, nitrous oxide, ether, and chloroform—might have been increased in number. The statement that death from chloroform generally results from cardiac failure is, we believe, incorrect, even according to those authorities who are positive in their belief that the drug acts as a cardiac depressant. Methylene blue and methyl blue, although considered as one and the same thing in this book, are not identical.

We regard this compilation as being distinctly better than the previous book of the same size upon the practice of medicine by the same author, but we do not believe that it is sufficiently thorough to take the place of larger works.

DISEASES OF THE RECTUM AND ANUS. By Charles B. Kelsey, A.M., M.D. Fourth edition, revised and enlarged. With two chromo-lithographs and sixty-two illustrations.

New York: William Wood & Co., 1893.

The teachings of this book may be considered as coming *ex cathedra*, since Kelsey is generally acknowledged to be the leading authority on diseases of the rectum and anus. The work is characterized throughout by a certain positiveness of teaching and directness of expression most gratifying to those of lesser experience who seek a reliable guide. Yet, though Kelsey makes his own views prominent and leaves no question as to what these are, he very fairly discusses the value of methods and treatment other than those which he himself prefers.

The first chapter is devoted to points of anatomy and physiology. This section, which might readily have been rendered prolix, is one of extreme interest, from the evident practical and clinical bearing of the points brought out. The second chapter is devoted to general methods of examination and operation and the choice of instruments and appliances, and represents the results of the wide practical experience of the author. These subjects are discussed with satisfactory detail, even the equipment of the surgical bag designed for operations on the rectum receiving careful attention.

Congenital malformations are discussed briefly, most space, as is proper, being devoted to surgical treatment.

The chapter upon fistula is perhaps the one of greatest interest in the work. The author insists that a fistulous tract must be followed by a careful dissection, and must not be laid open by a single sweep of the knife carried in the groove of a director which has been by more or less force made to enter by one opening and passed out at the other. The director need only be introduced a short distance at a time; thus side tracks are recognized as they are met. All such side tracks should be slit up, provided this can be done without the risk of incontinence of feces or destruction of the perineum in women, or too great injury for the reparative powers of the patient. Kelsey states that it is safe to divide both sphincters once in the median line without danger of incontinence. The treatment of horseshoe fistula is most ably discussed. The operation of freshening and suturing the sphincter when incontinence follows its too free division is described. In the treatment of fistula, Kelsey states that he rarely uses any dressing following that applied immediately after operation, but merely introduces a

finger into the wound two or three times a week to secure healing from the bottom. He condemns tight packing.

The chapter upon hemorrhoids is also one of peculiar value. The clamp and cautery represents the method of choice in removing these tumors. The carbolic injections are rejected as not sufficiently radical and as causing more pain than the clamp and cautery. After the clamp operation no dressing is applied, except a pad of oiled lint and a T bandage kept in place for a few minutes to arrest oozing from the preliminary incisions in the skin. Belladonna and opium suppositories are unnecessary. Thirty-six hours after operation a laxative pill or saline should be administered. The following morning an oil enema should be thrown into the rectum.

The Whitehead operation is described, but is not commended. The various operations and treatment most successful in prolapse and invagination are detailed at length. Non-malignant ulcers, venereal diseases of the rectum and anus, non-malignant stricture, and, finally, cancer are taken up in order. All the most recent operations for the relief of rectal cancer are to be found in this work, together with a section on the formation and closure of the artificial anus.

There is a chapter on constipation and fecal impaction, one on pruritus ani and wounds and foreign bodies, and, finally, one upon spasm of the sphincter and neuralgia.

This book is the best practical work on this subject to be found in any language. It is difficult to imagine how it could be improved.

A TEXT-BOOK OF THE DISEASES OF WOMEN. By Henry J. Garrigues, A.M., M.D.

Philadelphia: W. B. Saunders, 1894.

Garrigues is already widely known as an eminently practical gynecologist whose views are not too extreme to be followed by the large mass of his medical brethren who have not become specialists; hence this work of his is quite certain to have an appreciative reception. It is extremely satisfactory to find so much space and so many admirable illustrations devoted to the subject of normal and pathological anatomy. This is a feature worthy of imitation. The classification adopted by the author is one which will meet with favor both from the student and practitioner. The descriptions of special methods and operations are sometimes too brief to be of practical value. In describing the operation of ovariectomy, a rather formidable armamentarium is advised, in all about sixty-eight instruments. The further description of the operation is a very skilful piece of condensation. The book closes with an ap-

pendix on sterility. This subject is ably summed up in a few pages.

The special merits of this work are that it is a book of moderate size, and hence comparatively inexpensive, that it is thoroughly modern, that the subjects are so well tabulated and indexed that reference is easy, that the author's style is singularly concise and clear, and hence that to the ordinary busy man the latest treatment or the latest diagnostic points of any given disease can be discovered at the expenditure of a minimum of time. Moreover, the illustrations are copious and admirable. These merits are such that the work is sure to find a place for itself.

CHIRURGIE DES VOIES URINAIRES. ÉTUDES CLINIQUES.  
Par le Dr. E. Louveau. 2me édition.  
Bordeaux: Feret & Fils, 1894.

This work is arranged on no definite plan, but consists of reports of clinical cases recorded with an attention to detail which sometimes becomes slightly distressing. This book will be of some use to the active genito-urinary surgeon, but to the general practitioner it has but little value. The technique of some of the operations and procedures is interesting and instructive in the extreme. The author is to be congratulated on having produced, if not a text-book on this subject, at least a monument to his patient clinical research.

## Correspondence.

LONDON.

(From our Special Correspondent.)

At a recent meeting of the Physiological Society a communication was made by Messrs. Bokenham and Lewis Jones on the effects of electric-lighting currents on the economy. The authors originally undertook this research in order to get an explanation of the reason why, when a man became involved in an electric-lighting circuit, he was sometimes killed and sometimes suffered but little damage beyond local burns. The most interesting results obtained are those bearing on the mode in which death is caused by the passage of currents at high pressure. By laboratory experiments with guinea-pigs and cats, using a current of one hundred and five volts, they found that it was impossible to kill these animals by passing the current in any direction through the intact skin. To currents of this comparatively low intensity the skin offers such a great resistance as to greatly diminish the amount of

current actually passing through it, and reducing it to a perfectly safe amount. Continued passage of current at even this voltage did at length break down the skin resistance by a process of electrolysis, accompanied by considerable heating effect.

If a current of the same pressure were passed through the skull in any direction, the large electrodes used being applied to two points denuded of skin, still, a fatal result was unattainable. In fact, the only effect noticeable in an animal not too deeply anæsthetized was a partial return to consciousness, together with some stimulation of the respiratory centre and a slight rise of blood-pressure. If, however, the current were applied at points denuded of skin on the two sides of the thorax, so that it passed through the heart, death followed almost instantaneously, being indicated by a brusque fall of blood-pressure and one or two quivering heart-beats, the heart then stopping in full diastole. The respiration, after a very transient great increase of rapidity, ceases,—it may be for a minute,—a few gasping breaths, apparently the result of asphyxia on a not completely exhausted respiratory centre, making their appearance before the final complete relaxation of the animal. It would appear, therefore, that with this voltage, at least, death is due to the effect of the current on a vital organ,—the heart,—not on the central nervous system. If so, it follows that the use of electricity as a state engine of destruction should be directed to the heart rather than to the cerebral centres, as in the present method of electrocution. When, as in the case of capital punishment, currents of extremely high voltage are employed, their penetrating power is so great that the comparatively small resistance of the skin might practically be disregarded. This research is not as yet complete, but enough has been made out to show that the present mode of application of the electrodes for judicial purposes is by no means the best.

While on electrical topics, I may as well mention an innovation which I recently noticed at Moorfields Eye Hospital. Until now the ophthalmoscope-room, which has accommodation enough for about a dozen patients to be examined simultaneously, has been provided only with the old-fashioned and extremely hot Argand burner as a source of light. On account both of the heat given out and the extent to which gas and patients vitiated the atmosphere, a morning of ophthalmoscopic work was an almost certain means of acquiring a bad headache; at least that was my experience, running now over several years. The evils above

alluded to have now been removed in great measure by the introduction of the electric light, which has been rendered suitable for the purpose by the well-known opticians, Curry and Paxton. The difficulty caused by the narrowness of the incandescent filament in the ordinary lamps has been obviated by the introduction of "focal" lamps, possessing many close spiral twists, the globes of these being also gray-ground, so that a good surface of light is obtainable in all positions of the lamp bracket. In order to render this arrangement suitable for the display of vitreous opacities and other appearances which can only be detected by a rather subdued light, the inventor has arranged a series of resistances in the form of a tube embracing the movable arm of the bracket. In order to throw one or more of these into circuit and thus reduce the intensity of the light, all that has to be done is to turn a small milled collar which occupies the usual position of the gas-tap. I have used this arrangement for many hours, both at hospital and in my own consulting-room, and find it most satisfactory and free from the inconveniences which attend the use even of the most perfect gas arrangement.

Can any reader tell me anything as to the significance of a case which I observed only a few days ago? The patient, a child of about nine years old, was brought in complaining of defective vision. On ophthalmoscopic examination, two or three largish pigmented patches, distinctly raised, were found, almost symmetrically arranged to the temporal side of the disk. I certainly had never seen a case like it before, and several who have seen it have expressed the opinion that the patches seen are retinal moles. What is their pathological significance?

---

### Notes and Queries.

---

#### CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS. THIRD TRI- ENNIAL SESSION.

WASHINGTON, D. C., March 8, 1894.

#### CIRCULAR NO. 1.

The Congress meets in Washington, D. C., May 29 to June 1, inclusive. It is composed of the members of those national medical societies whose names and secretaries are given below, and of guests specially invited by the Executive Committee.

To enable a physician residing in the United States to become a member of the Congress,

with the right to participate in its proceedings, it is necessary that he be a member of one of these constituent national societies.

A physician may be accredited as a visitor to the Congress by any one of the constituent societies. The certificate of the secretary of one of these societies to the effect that he is thus accredited will enable him to register upon payment of the registration fee, which registration will entitle him to a card of admission to the reception and to a copy of the Transactions of the Congress, but not to take part in the deliberations of the Congress.

The following are the names of the constituent societies in the order of date of their organization, and the names and addresses of their respective secretaries, to whom inquiries as to mode of obtaining membership should be addressed:

American Ophthalmological Society, Secretary, S. B. St. John, M.D., Hartford, Conn.; American Otological Society, Secretary, J. J. B. Vermyne, M.D., New Bedford, Mass.; American Neurological Association, Secretary, Graeme M. Hammond, M.D., 58 West Forty-sixth Street, New York City; American Gynecological Society, Secretary, H. C. Coe, M.D., 27 East Sixty-fourth Street, New York City; American Dermatological Association, Secretary, Charles Warren Allen, M.D., 640 Madison Avenue, New York City; American Laryngological Association, Secretary, Charles H. Knight, M.D., 20 West Thirty-first Street, New York City; American Surgical Association, Secretary, J. R. Weist, M.D., 118 North Eighth Street, Richmond, Ind.; American Climatological Society, Secretary, J. B. Walker, M.D., 1617 Green Street, Philadelphia, Pa.; Association of American Physicians, Secretary, Henry Hun, M.D., 33 Elk Street, Albany, N. Y.; American Association of Genito-Urinary Surgeons, Secretary, J. A. Fordyce, M.D., 66 Park Avenue, New York City; American Orthopædic Association, Secretary, John Ridlon, M.D., 103 State Street, Chicago, Ill.; American Physiological Society, Secretary, W. P. Lombard, M.D., Ann Arbor, Mich.; Association of American Anatomists, Secretary, D. S. Lamb, M.D., 800 Tenth Street, Washington, D.C.; American Pediatric Society, Secretary, Samuel S. Adams, M.D., 1632 K Street, Washington, D.C.

All physicians are invited to attend the meetings of the Congress and the public meetings of the societies, but only those may register who are members, specially-invited guests, or visitors accredited through the secretaries of constituent societies.

The registration office will be in Parlor I of The Arlington. From this office the mail of members and invited guests will be distributed, and here the city address of each member, guest, and accredited visitor can be ascertained. All members, invited guests, and accredited visitors should register as soon as possible.

A registration fee of five dollars will be required of all members and accredited visitors. Invited guests will register, but will pay no registration fee. A copy of the published Transactions of the Congress will be sent to all members, and to each invited guest and accredited visitor who is registered.

Only those who register, and the ladies accompanying them, will be admitted to the reception.

It is recommended that members effect registration in advance of the meeting by filling out the blank certificates of registration which will be sent to each member about May 15, and forwarding these certificates, with the requisite fee, to Dr. John S. Billings, Treasurer of the Congress.

The sessions of the Congress will be held from 2 to 5 P.M., daily, in the Metzgerott Music Hall, corner of Twelfth and F Streets.

The sessions of the societies will be held according to the programmes of each, as follows:

American Ophthalmological Society, Ladies' Parlor, No. 2, The Arlington; American Otolological Society, Ladies' Parlor, No. 1, The Arlington; American Neurological Association, Cosmos Club; American Gynecological Society, Lecture Hall, Columbian University, corner Fifteenth and H Streets N.W.; American Dermatological Association, New Reception-Room, The Arlington; American Laryngological Association, Parlors D and E, The Arlington; American Surgical Association, Main Hall, Preparatory Department Columbian University, H near Fourteenth Street; American Climatological Association, Parlor, Wormley's Hotel; Association of American Physicians, Hall No. 2, Columbian University, corner Fifteenth and H Streets; American Association of Genito-Urinary Surgeons, The Shoreham; American Orthopaedic Association, Preparatory Department Columbian University, H near Fourteenth Street; American Physiological Society, Physical Laboratory Columbian University, Fifteenth and H Streets; Association of American Anatomists, Preparatory Department Columbian University, H near Fourteenth Street; American Pediatric Society, Parlors A and B, The Arlington.

The President of the Congress, Dr. Alfred L. Loomis, of New York, will deliver an address Thursday evening, May 31, at 7.30 P.M. Subject: "The Influence of Animal Experimentation on Medical Science."

The Executive Committee has decided that the Congress shall give a dinner on Wednesday evening, May 30, at The Arlington, to which its guests will be invited. It being its desire to make this a general affair, it is hoped that all members of each of the constituent societies will subscribe to it. The subscription, *ten dollars*, should be sent to the chairman of the Committee of Arrangements as early as possible, to avoid confusion. The list must be closed by May 25.

No provision having been made for Tuesday evening, May 29, that evening is at the disposal of the different societies for business or social purposes.

The committee will take pleasure in answering any inquiry relating to the local arrangements of the Congress.

#### OFFICERS OF THE CONGRESS.

*President*, Alfred L. Loomis, M.D.

*Vice-Presidents, ex officio*, Presidents of Constituent Societies.

*Chairman of Executive Committee*, Landon Carter Gray, M.D., New York City.

*Treasurer*, John S. Billings, M.D., Washington, D.C.

*Secretary*, William H. Carmalt, M.D., New Haven, Conn.

#### COMMITTEE OF ARRANGEMENTS.

Samuel S. Adams, M.D., *Chairman*, 1632 K Street N.W., Washington, D.C.; John S. Billings, M.D., Army Medical Museum, Washington, D.C.; W. W. Johnston, M.D., 1603 K Street, Washington, D.C.; Irving C. Rosse, M.D., The Albany, Washington, D.C.; S. O. Richey, M.D., 732 Seventeenth Street, Washington, D.C.; J. Taber Johnson, M.D., 1728 K Street, Washington, D.C.; William H. Welch, M.D., Johns Hopkins Hospital, Baltimore, Md.; I. E. Atkinson, M.D., 605 Cathedral Street, Baltimore, Md.; T. Morris Murray, M.D., 730 Seventeenth Street, Washington, D.C.; D. W. Prentiss, M.D., 1101 Fourteenth Street, Washington, D.C.; Samuel Theobald, M.D., 304 Monument Street, Baltimore, Md.; Henry G. Beyer, M.D., Naval Academy, Annapolis, Md.; De Forest Willard, M.D., 1818 Chestnut Street, Philadelphia, Pa.; Frank Baker, M.D., 1315 Corcoran Street, Washington, D.C.

### THE INDIAN MEDICAL CONGRESS.

The proposal to have a Medical Congress in India was considered at a meeting of the Council of the Calcutta Medical Society on January 24, when it was decided that an "Indian Medical Congress" shall be held in Calcutta at the beginning of January, 1895. The preliminary arrangements were discussed and a general plan sketched out. It was decided that in each province local secretaries, native as well as European, should be asked to co-operate with the Calcutta secretaries, and it was further decided that the sections into which the Congress should be divided should be,—

1. Medicine, including Pathology.
2. Surgery.
3. Obstetrics and Diseases of Women and Children.
4. Public Health.
5. Medico-Legal Medicine and allied Subjects.

Further details will be given in a future issue. It was decided that the Congress should be widely advertised, and that all medical men practising in every part of the world, but especially in India and the East, should be invited to take part in it and submit papers to be read in the different sections.

### AMERICAN MEDICAL ASSOCIATION.

The Committee of Arrangements has secured Odd Fellows' Hall Building, corner Market and Seventh Streets, San Francisco, Cal., for the meeting June 5, 1894.

Assembly Hall, for the general meeting, has a capacity of fifteen hundred; the twelve smaller halls, for section work, range in capacity from five hundred downward, with committee-rooms adjacent.

The engagement carries three of these rooms on Monday for accommodation of associate organizations, as that of the editors, colleges, etc.

The banquet-room on the ground floor, sixty-five by ninety-five feet, will be devoted to exhibition purposes, for which it is admirably adapted, and has been secured for the entire week, that exhibitors may have Monday in which to place their goods and Saturday in which to remove them. Nearly half of the space is already taken, and others who desire to make a display of their goods under the most auspicious circumstances ever presented on the Pacific coast should lose no time in applying to the chairman for space.

Head-quarters for the Association have been

located at the Palace Hotel, corner Market and Montgomery Streets, only four blocks from the place of meeting. Here we have "Marble Hall," thirty by forty feet, as a registration-room, where work will begin on Monday, and "Parlor A" for committee work.

The following hotels, centrally situated and convenient to the place of meeting, have quoted special rates for members and their families, which will apply during the entire stay of the guests, who should, upon registering, signify that they are in attendance upon the meeting of the Association.

The rates quoted are for single persons, the variation depending upon the size, situation, and appurtenances of the rooms, as single, *en suite*, with private bath, etc. Special arrangements will be made for families or parties on timely notice.

Some of the hotels entertain upon the American plan only, some upon the European plan only, and some upon either plan to suit guests.

Palace Hotel (head-quarters), American plan (rooms and board), \$3.50 to \$5.50 per day; European plan (rooms only), \$1.50 to \$3.50 per day.

Baldwin Hotel, American plan, \$3.50 to \$5.00 per day; European plan, \$1.00 to \$3.00 per day.

California Hotel, American plan, \$3.50 and up per day; European plan, \$1.50 and up per day.

Lick House, American plan, \$2.50 and up per day; European plan, \$1.00 and up per day.

Russ House, American plan, \$2.00 to \$3.50 per day; European plan, 50 cents to \$2.00 per day.

Occidental Hotel, American plan only, \$2.50 and up per day.

Hotel Pleasanton, American plan only, \$2.50 to \$5.00 per day.

Grand Hotel, connected with the Palace by a glass inclosed bridge across New Montgomery Street, European plan only, \$1.00 to \$2.00 per day.

In addition, there are many other hotels, boarding-houses, lodging-houses, and restaurants contiguous to the place of meeting, where one can be made happy and comfortable at less cost.

Post-office, Section K, is located in the Palace Hotel, on the office floor, adjacent to the registration-room, where members can receive all mail matter by having it so addressed.

More anon,

R. H. PLUMMER,

Chairman.

### PILOCARPINE IN ERYSIPELAS.

By G. WALTER BARR, M.D.,  
Professor of Materia Medica, Therapeutics, Public Hygiene, and  
State Medicine in the College of Physicians and Surgeons,  
Keokuk; Physician to Mercy Hospital, etc.

THE recent article on pilocarpine administered hypodermically in erysipelas,\* by Dr. Salinger, has its main facts corroborated in my own experience. In 1883 I heard Professor J. M. Da Costa teach the use of pilocarpine carefully administered for this disease,

and have used it ever since with the most gratifying results. It has failed but once in my hands, and then probably for reasons which will be elaborated later. After a small experience with the method of dynamic doses administered at regular intervals, I am constrained to retain the details of Da Costa's method as giving best results. This is the administration of a dose sufficient to produce a marked physiological action, repeated in two hours, again in six hours, and finally in two hours more—i.e., in two, eight, and ten hours from the initial dose—with the hypodermic syringe. I think I have discovered that the efficacy of this treatment depends upon the time which has elapsed from the inception of the first symptoms of the

\* THERAPEUTIC GAZETTE, March 15, 1894, p. 154.

disease. My most brilliant successes have been in the cases seen very early, and the only failure in a case of a week's standing, while the time required to effect a cure has been in direct ratio to the duration of the disease before the treatment began. The rule has been that in twelve hours from the first injection local convalescence is established and the systemic symptoms are rapidly disappearing. In cases seen later it has been necessary to repeat the whole procedure after an interval of six or eight hours from the last dose. In no case, except the one mentioned, has it been necessary to further repeat the hypodermic injections, although I continued fluid extract of pilocarpus per orem in a number of cases as a precautionary measure. The average duration of the disease has been about three days. In one case erysipelas attacked the location of an epithelioma as large as an egg upon the cheek of an old man, the symptoms being typical and well marked, and the characteristic inflammation of the skin extending over the frontal region. The objective inception occurred one evening; the extension of the skin pathology had reached the above extent by noon of the next day, when the treatment began. Twenty-four hours afterwards the disease had apparently disappeared, and a day later, or forty-eight hours after the acme of the objective signs, I removed the superior maxillary bone, which I found involved by the epithelioma, as well as much of the cheek; there was no return of the erysipelas. I have noticed no difference in the results in cases certainly traumatic from those in cases apparently idiopathic.

The dose used has been sufficient to cause sweating and salivation, and  $\frac{1}{6}$  grain usually in the beginning. In the case in which it failed the drug was pushed as far as the cardiac depression would allow. In different individuals pilocarpine produces a variable amount of effect upon secretion in the skin and the salivary glands, sometimes one and sometimes the other dominating. I have been unable to distinguish a difference of therapeutic effect, depending upon the quantity of perspiration as distinguished from the quantity of saliva excreted. When the dynamic action of the drug was manifested by great salivation and little perspiration, the remedial effect was apparently the same as when the perspiration was great in quantity and the salivation less; this seems to dispose of the hypothesis of Salinger that the sweat washes out the bacilli through the enlarged pores. How the drug cures erysipelas I have been especially anxious to discover; it has been an unsuccessful quest. It seems prob-

able that somewhere in the sympathetic nervous system the secret is hid, but each hypothesis has been discarded in turn. Perhaps light will ultimately come through the pathologist and more definite data about the disease.

I have been surprised at finding practically nothing in medical literature on this subject. No claims to originality are made. I learned the method from Da Costa's lectures in the Jefferson Medical College, and as Salinger gives him credit as the originator, to him is the honor due. To corroborate the clinical experience of Salinger and to emphasize the necessity of full dynamic doses, repeated at certain intervals, and the early initiation of the treatment, is the object of this paper, which is based on about forty cases.

#### *THE DIFFERENT FORMS OF DIABETES MELLITUS, WITH REMARKS ON TREATMENT.*

A CLINICAL LECTURE DELIVERED AT THE PHILADELPHIA HOSPITAL, WITH ADDITIONS FROM A CLINICAL LECTURE DELIVERED AT THE POLYCLINIC HOSPITAL.

BY SOLOMON SOLIS-COHEN, M.D.,  
Professor of Clinical Medicine and Therapeutics in the  
Philadelphia Polyclinic; Visiting Physician  
to the Philadelphia Hospital, etc.

**G**ENTLEMEN:—These two patients are brought before you that they may be compared and contrasted. What is the first point of difference between them noted by the class? Some one answers correctly that one is very stout and the other very thin. What other difference is there? Again, I am correctly answered that the stout patient appears to be much older than the thin patient. Inquiring now for specific data as to these differences in age and weight, we learn that Philip M. is sixty-seven years old, and weighs now, as for many years, two hundred and five pounds; while Peter M. has not quite completed his thirtieth year of life, and weighs at present but one hundred and twenty pounds, having lost about sixty-five pounds in some eighteen months.

Peter is a native of Ireland. His father, always strong and hearty, died of an acute illness, the nature of which he does not remember. His mother died of old age. So far as he knows, there is no history of gout, rheumatism, cancer, consumption, or neurosis in the family. It will not do, however, to lay too much stress on negative evidence in the cases of patients of this class. Peter has been a hard drinker for ten years. Beer is his "favorite vanity," and he used to get drunk

regularly every fortnight. He denies any venereal disease, and we find no evidence of syphilis. For several years, in the course of his daily work as a wagon-driver and stevedore, he has been exposed to all vicissitudes of weather. He fractured his right humerus sixteen years ago and again three years ago. With this exception, he knows of no serious illness or injury previous to the gradual loss of strength and weight, which he dates back about two years. Until then he had weighed one hundred and eighty-five pounds, was strong, and considered himself healthy. After he began to fail he noticed that he was passing water more frequently and in greater quantity than formerly. He was troubled with inordinate thirst, that neither beer nor water could quench. Six months ago his craving for food became similarly insatiable.

While general feebleness has been progressive, for about a year there has seemed to be especial weakness in the muscles of the legs. He is quickly fatigued by walking or by mounting stairs, and recently he complains of almost constant dull, aching pain from the knees down. For some three months there has been soreness and a sense of muscular feebleness in the lumbar region, and sexual power has been lost for about the same length of time.

He had not sought medical aid prior to his admission to this hospital, February 2, 1894, when the following notes of his physical condition were made by the resident physician, Dr. Stewart:

"The patient is moderately tall and slim, even emaciated; weight, one hundred and twenty pounds. The bony framework of the chest is prominent through loss of soft tissues. There is much depression both above and below the clavicles. The circumference of the chest at the nipple line, on forced expiration, is thirty-two and a half inches; on forced inspiration, thirty-three and a half inches. There is an up-and-down movement of the thorax as a whole, and breathing is principally diaphragmatic. There is supraclavicular dulness, especially on the right. There is some fulness of the chest, anteriorly, above the nipple line, and percussion elicits high-pitched tympany, more marked upon the right. Percussion note is impaired below the nipples on both sides. Posteriorly, there is hyper-resonance on percussion over both sides of the chest. On auscultation there is found over the upper portion of both lungs, anteriorly, bronchial breathing, with much-prolonged expiration; the quality is more tubular at the left. Over the lower portion on both sides the breathing is harsh and

somewhat puerile in quality. Posteriorly, the breathing is exaggerated, and there are a few sonorous râles at the left upper chest. Vocal resonance is exaggerated, especially over the upper part of the right chest, anteriorly, and vocal fremitus is likewise increased. Liver dulness is diminished. Splenic dulness cannot be well made out. Cardiac dulness is slightly diminished. The apex-beat of the heart is feebly discernible on inspection and palpation, in the fifth interspace, slightly inside the nipple line. The heart's action is rapid (84) and feeble. The first sound is short and impure, wanting in clearness and force, and the second sound, while relatively accentuated, lacks tone. There is general muscular wasting, especially in the legs. The grasp of the hands is enfeebled. There is no tactile, dolorous, or thermic anæsthesia. Knee-jerk is lost on both sides. Muscle-jerk can be developed on right side, but is absent on left. There is no ankle clonus. Pain is complained of, and there is tenderness to pressure in both calves and in the thighs along the course of the sciatic nerves. The soles of the feet are exquisitely tender, and the patient states that they frequently 'fall asleep,' with tingling as of 'pins and needles.' There is no pain or tenderness in the upper extremities. The site of fracture at the lower third of right humerus is marked by considerable callus. Gait and station are normal. There is no vertigo or loss of vision. There is no pruritus."

He tells us that he has not had furuncles or ulceration of the throat. He has an easy daily stool. His tongue is red at the edges, flabby, and coated with a whitish fur, in which appear bare, red, glazed patches. He has some belching, water-brash, and flatulence, though these symptoms have lessened since his diet was regulated.

Now, what further data do we need before diagnosing this case? A member of the class answers, "The urine should be examined." And what would you expect to find in the urine? "Sugar, and possibly albumin and casts," is the correct reply. We have not found albumin or casts, but we have found a large quantity of sugar, within a small fraction of ten per cent. before regulation of diet and nearly six per cent. since the diet was restricted. As the man passed two hundred and fifty to two hundred and sixty-five ounces of urine, and is still passing about one hundred and sixty ounces, daily, this means an average daily excretion of nine and a half ounces of sugar, even under dietetic treatment.

The diagnosis, then, is, as the class sug-

gests, *diabetes mellitus*; but we have also some complicating conditions." The pain, tenderness, and disturbances of sensation in the lower extremities, together with the loss of knee-jerk, point to a polyneuritis which may be alcoholic in this instance, but which is not uncommon in diabetics. Indeed, double sciatic neuritis, such as this patient presents, should always make the physician suspect the existence of *diabetes mellitus*. We will have electrical examination of the muscles made for completeness of record. The pulmonary conditions seem at first somewhat confusing and contradictory. On further questioning, the man tells us that he has had shortness of breath on exertion for some time, and that it is increasing, but he has attributed this to general weakness. He likewise answers that he has occasional cough and expectoration. Dr. Stewart supplements this with the record of examination of the sputum, which is, however, negative,—that is to say, neither lung-tissue nor tubercle-bacilli were found. The sputum is muco-purulent. I think we are justified, from the physical and rational signs taken together, and with our knowledge of the usual course of events in diabetes, in concluding that there is beginning tuberculous infiltration in the emphysematous lungs of this patient. This combination of tubercle and emphysema will account for the apparent contradictions in the percussion phenomena. The heart is evidently dilated, and probably as a result of three causes,—emphysema, diabetes, and alcoholism. The liver is probably cirrhotic as a result of alcoholism. As yet there is no œdema and no ascites. The combination of diabetes and cirrhosis of the liver is not common, and is, I think, a mere coincidence. Conditions leading to enlargement of the liver are more frequently causally related with diabetes. I should not be surprised to find evidences of nephritis, but they have not yet been discovered. We will have his eyes examined to see whether he has either albuminuric retinitis or any of the characteristic lesions of diabetes.

Philip M. is a German by birth, is sixty-seven years of age, and has been a shoemaker. He, too, has generously indulged his liking for beer. The record states that he drank fifty or sixty glasses a day, but I don't suppose that means every day. At all events, he hasn't had anything like that much since his entrance into the hospital, April 12, 1893.

At that time he complained of dyspepsia, shortness of breath, and hemorrhoids. He then stated that his father had been affected similarly, and had died at the age of fifty-nine.

His mother had been subject to attacks of dyspnoea, and died from an unknown cause. Two brothers were living, one healthy and one in about the same condition as himself. He knew nothing as to hereditary diseases in his family. He states that he has had none of the diseases of childhood. As a young man he had a severe attack of acute articular rheumatism, and ever since has had milder attacks at varying intervals. Ten years ago he had lobar pneumonia. At different times during the last fifteen years he has had œdema of the lower extremities. At one time—we can get no more definite data—he had epileptic attacks, falling unconscious, frothing at the mouth, biting the tongue. The attacks were preceded by an aura, a "warm wave" passing up the back of his neck to his head. They were followed by transient loss of vision. He has had no attack for two years.

At the time of admission the physical examination of the patient showed the liver to be considerably enlarged, smooth, and resistant. The heart was slightly enlarged, slow, and feeble, the sounds indistinct. My colleague, under whose care he came, made a diagnosis of fatty liver and fatty heart, and instituted appropriate treatment. Nothing significant was found in the urine until some six months ago, when, in the course of routine examination, it was found to contain considerable sugar. There was not then, and is not now, excessive thirst; appetite is good, but not inordinate; there has been no furunculosis, no ulceration of mucous membranes, no pruritus. There is polyuria, ninety to one hundred ounces *per diem*, but it appears that the patient had not noticed this fact until told to measure his urine before dieting and after dieting. At present there is about two and eight-tenths per cent. of sugar in the urine.

The diagnosis, therefore, as in our other case, is *diabetes mellitus*; but unless the urine had been examined in regular course, there was nothing in the clinical history of the case, so far as learned from the patient, to suggest this condition, which has apparently developed since the patient's entrance into the hospital.

We will now allow the patients to leave the room, and continue our discussion of the resemblances and contrasts they exhibit. Both present the urinary phenomena of *diabetes mellitus*,—that is to say, they both persistently pass an abnormally large quantity of urine, which persistently contains sugar. Beyond this, however, there is little in common in the two cases. Philip passes only about twice the normal quantity of urine, and the average quantity of sugar

excreted daily is less than three ounces ; neither thirst nor appetite is excessive ; he is apparently well nourished, and despite the serious organic lesions discovered in his case his countenance does not exhibit any sign of distress. Peter passes an average of one hundred and sixty ounces of urine and nearly ten ounces of sugar daily. He is tormented with inappeasable thirst and with a craving for food that cannot be satisfied. He is rapidly wasting, his strength is failing, and anxiety is plainly written upon his face.

The French writers especially insist upon the difference between diabetes in the obese and diabetes in the emaciated, and that difference, it is held, is not merely one of degree, but of kind. Thus, in the cases before us it seems extremely probable that the nutrition of one patient has not suffered so much and that of the other so little in comparison merely because the one has a "more severe case" than the other of the same morbid process ; but that the differences in the general clinical phenomena in the two cases are fundamentally connected with the emaciation in the one case and with the obesity in the other case ; and that the morbid process in the case of the young and wasted man is unlike that in the case of the elder, well-preserved man. In other words, glycosuria, or the combination of polyuria and glycosuria, does not constitute a disease, but, like albuminuria, is merely a symptom that may occur in connection with several diseases, and the entire phenomena of the case—the rational symptoms—must be taken into consideration in diagnosis, prognosis, and treatment. All of the causes that may give rise to diabetes mellitus have not yet been discovered. It has followed infectious diseases, malaria in rare instances, influenza and syphilis more frequently. In such cases there is at least a remote toxic origin, but the mediate mechanism may be neural or visceral. So, too, in a class of cases frequently met with,—those in which the uric-acid diathesis or gouty dyscrasia seems to bear a causative relation to temporary glycosuria or to persistent saccharine diabetes,—while the noxa in the blood and tissues may be a remote excitant of the diabetic complexus, the mechanism of its production is probably neural or visceral, or, perhaps more correctly, neuro-visceral. When it shall have been decided whether or not gout is a neurosis, and what are the true relations of gout with disease of the liver, and whether hepatic disorder in gout is secondary to nervous disorder or the reverse, the problem in relation to diabetes will likewise be simplified. For diabetes may be produced ex-

perimentally through the liver or through the nervous system, or through the liver by way of the nervous system, as in Claude Bernard's celebrated experiment, and pathologically it is sometimes found associated with hepatic disease and sometimes with disease of the brain or of the sympathetic nervous system. Sometimes, however, no significant lesion is found at necropsies upon the subjects of diabetes.

But there is still another organ of great importance in the study of the etiology and pathology of diabetes, and more particularly in relation with what the French term *diabète maigre*,—diabetes with emaciation. That organ is the pancreas. Lancereaux long ago called attention to the comparative frequency with which lesions of the pancreas were found in cases of *diabète maigre*, and the recorded instances of such association are rapidly accumulating. When we remember that diabetes is not a common disease, though my personal experience would lead me to believe that its frequency is much underestimated and that many cases go unrecognized ; when we remember, too, that necropsies are not always to be obtained, the number of recorded cases exhibiting pancreatic disease seems to be comparatively large. The lesion is usually sclerosis,—that is, interstitial pancreatitis,—with atrophy of the glandular tissue, and frequently with the presence of calculi and sand. Sometimes the duct of Wirsung is completely blocked with calcareous matter. Cystic and cancerous disease of the pancreas have likewise been associated with glycosuria and with diabetes mellitus. Furthermore, experiments made by Martin, Lépine, Von Mering and Minkowsky, and others have established the fact that, in dogs, extirpation of the pancreas, or artificial production of complete atrophy of the gland, will cause diabetes mellitus, while if a certain-sized portion of the gland be left uninjured, or if a graft of a certain-sized portion of pancreas be made in the abdomen of the animal, these symptoms either fail to develop or rapidly disappear. It has been claimed by Thierloix that injury to the semilunar ganglion, to the solar plexus, or to the nerves connected with the pancreas has had much to do with the experimental results cited ; but while he has proved that such injury may give rise to diabetes, the other experimenters named have apparently proved that diabetes may likewise be produced when injury to nerves has been carefully guarded against. So that present evidence goes to show that destruction of the pancreas, or of certain neighboring and attached nerves and ganglia, or of both pancreas and nervous structures, will cause in dogs

polyuria, glycosuria, polyphagia, and polydipsia, with progressive inanition and death; in other words, the phenomena of diabetes mellitus.

In the human being, general experience seems to show that diabetes in obese patients is usually gouty or hepatic in origin; in emaciated patients it is usually associated with nervous or pancreatic lesion, or, according to Thiroloix, is always neuro-pancreatic.

In such subjects, when a toxic origin cannot be assigned, and I include alcoholism among toxic causes, it will usually be found that they have been much exposed to cold weather, or that they have been subjected to severe mental or emotional strain, often, in the case of men, to both mental and emotional strain, as in the conduct of large enterprises involving overwork, anxiety, and fluctuations of spirit due to alternations of success and disappointment. The disease, it is true, is more common among women than among men, but if I may trust my own experience, women are more likely to exhibit the type of *diabète gras*,—diabetes with obesity. Thus, of seven diabetics now under my care in hospital and private practice, three are men, four are women; five are obese, of whom two are men and three are women. You have just seen one of the emaciated patients, and the other is not only the only woman exhibiting *diabète maigre* whom I have seen in the last five years, but she is a woman of business, of great activity. A farmer's wife, she runs the farm and a hennery and a dairy; comes into market twice a week, and stands there from early morning to late afternoon, disposing of her produce; and, until I forbade it, was in the habit of beginning her market-day drives into the city at three o'clock in the morning. She will not give up any of her work. The most that I could do was to get her to come to town the afternoon before market-day. I mention these details simply to show the type of persons who are liable to *diabète maigre*. One other point is worthy of mention. She has always had a great craving for sweet things, and you will often elicit this fact in men as well. I am not prepared to say positively whether this craving is itself an early indication of morbid tendency, or of actual disease too slight to give rise to urinary symptoms, or whether the indulgence in sweets is one of the factors that help to cause the disease in nervous persons; but I am more inclined to the opinion that the craving is from the first morbid. At all events, the fact is worth remembering. It is said, and I believe with reason, that persons of the Hebrew race are especially liable

to diabetes mellitus. The explanation of the fact lies, I believe, in the high nervous tension caused by the centuries of persecution to which my people have been subjected, together with the greater development of mental and emotional than of physical nature which has always characterized them. But the strain of modern business life, especially in America, is causing diabetes to increase among all classes of the population, and in my own practice the number of Jews affected with this disease has been far less in actual count and no greater in proportion than that of persons of other races.

To return to our two patients. The difference in years between them is of great import in prognosis. Persons in whom the symptoms of diabetes mellitus develop before the age of forty recover so rarely that we may say the prognosis is absolutely bad. Persons who have passed the fortieth year of life before the symptoms develop recover so frequently that we may call the prognosis generally good. In both classes of cases, of course, individual conditions must be considered in estimating the degree of the favorable or unfavorable prognosis. Thus, while I have used the case of Philip M. in illustration of a certain group of cases in which the prognosis under favorable surroundings is usually good, yet the complications of the case and the comparatively large excretion of sugar which recurs from time to time make it of rather more serious prognosis than is usual in obese and elderly patients.

But before going further, let us see what we mean by recovery. Some cases are so mild that by simply instituting certain dietary restrictions, sugar disappears from the urine and the patient's general health and comfort are fully restored. Other cases require in addition some medication, temporary or continuous. Let the patient, however, disregard the dietary restrictions for any length of time and all the symptoms will return. There are exceptions to this rule, of course, but it is the general experience in the vast majority of cases of genuine diabetes mellitus. There are cases of mere temporary or intermittent glycosuria, or even glycosuria and polyuria, occurring, as a rule, in the obese, the elderly, and the gouty, and usually due to overeating, quantitative or qualitative, in which temporary restriction in diet will suffice, but we are not now considering such cases. By recovery, therefore, I mean a condition in which, under moderate dietetic restriction, sugar is absent from the urine, which is of normal quantity, and the patient is generally comfortable; but in which serious dietetic error will nevertheless bring about a renewal of symptoms. There is also a

condition of partial recovery, in which the patient continues to excrete a moderate quantity of sugar, say one or two per cent., the quantity of urine being slightly increased, say two quarts or a little more, and yet general health is apparently good. Patients may live to or beyond the Scriptural limit of threescore years and ten under these conditions, and probably in some instances their days are rather lengthened than shortened by their diabetes, because of the additional care they take of themselves. Now, provided the patient can and does take proper care of himself, the prognosis as to recovery or partial recovery, as I have defined these terms, is excellent if the patient be somewhat advanced beyond middle life when symptoms first appear, and good in all who have passed forty-five years, in the absence of specially unfavorable signs in the individual case. As a rule, the older the patient the better the prognosis, the younger the patient the worse the prognosis. Furthermore, the preservation of obesity is favorable, emaciation is unfavorable. Certainty that the case is of organic nervous origin is unfavorable, and functional neurosis is likewise unfavorable unless the exciting cause of nervous trouble—the overwork or anxiety—is removable; in which case, if the removal of the cause be not too late, the prognosis may be very good. Cases due to disease of the pancreas are of unfavorable prognosis. As a matter of course, the severity of special or general symptoms and the effect of diet and of other therapeutic measures modify the prognosis in individual cases.

The causes of death are most frequently pneumonia, pulmonary tuberculosis, and coma. The duration of unfavorable cases is from a few days to about five years, and I have known of favorable cases in which symptoms have been recognized for more than twenty years. In every case we must be on the alert to guard against coma, which may sometimes be precipitated by trifling causes, such as indigestion or slight chilling. In one case under my care the patient lay in a semi-comatose condition for three days following an attack diagnosed by the previous attendant, a homœopathist, as "malaria," but which seemed to me to be an instance of the intermitting variety of influenza. This patient, I was told, had passed sugar in her urine for fifteen years prior to the attack noted, which occurred three years ago, and she is still living and well. What warned me to expect coma and to try to guard against it was the sudden disappearance of sugar from the urine. This is always a bad sign, not a good one. At the same time the urine reacted

with ferric chloride, showing the presence of diacetic acid or  $\beta$ -oxybutyric acid, and was scanty in quantity. The therapeutic indication was the administration of warm drinks, alkaline diuretics, and diaphoretics, and the application of heat externally. Persistence in this course averted the development of complete coma, which would probably have been the precursor of death.

Throughout the management of a case of diabetes mellitus, therefore, examine the urine at regular intervals, not too far apart, and whenever its acidity increases, or the sugar is suddenly diminished or absent, or the wine-red color is developed by ferric chloride, administer alkalies freely until the urine is alkaline and the sugar reappears. Sodium bicarbonate may be given, or, if the quantity of urine is lessened, potassium acetate or potassium citrate, or some other diuretic. Some authorities, however, caution against potassium salts, believing them to be too depressing to the heart. Rochelle salt is often useful, because it will act either as a mild hydragogue purge or as a diuretic. And this leads me to say that constipation is often a precursor of diabetic coma, perhaps a cause. Never permit your patients, then, to be constipated. I am in the habit of giving to diabetic patients sodium phosphate in bulk, and directing them to take one or two teaspoonfuls in hot water before breakfast, or perhaps even two or three times a day, the quantity and frequency to be varied according to the effect upon the stools. Bartholow, indeed, recommends sodium phosphate as a remedy for diabetes mellitus, especially in obese subjects with hepatic disorder. Sometimes he combines with it sodium arsenate,  $\frac{1}{4}$  grain to the drachm of sodium phosphate. This is a useful expedient. Arsenic is itself useful in the treatment of diabetes mellitus. Lithium salts and various alkaline mineral-waters are useful to keep the secretions active and neutralize acidity. Recently I have been using the salts of strontium, and especially strontium bromide, in the treatment of lithæmia and in the treatment of diabetes mellitus in the gouty and obese. In doses of about 30 grains, with 20 drops of glycerin, and infusion of gentian to make a tablespoonful, three times a day, before meals, I have found this drug of great service. It is a stomachic tonic, promotes digestion and relieves flatulence, increases general nutrition, and quiets the nervous system; at the same time it keeps the blood moderately alkaline. It can be given for much longer periods continuously than is safe with potassium salts, and is not contra-indicated in lithæmic cases, as

most sodium salts are. Strontium lactate is likewise used, but I prefer the bromide. In gouty and rheumatic cases especially, but likewise in hepatic cases, sodium salicylate is useful. It can be alternated with strontium bromide, and I am in the habit of giving it for a week or two whenever the patient complains of arthritic or muscular pains. I prefer to give it in capsule, followed by an ounce or two of water, the dose being from 5 to 15 grains three times a day. From time to time strychnine arsenate,  $\frac{1}{12}$  grain six times a day, is given as a general nervous tonic-stimulant.

In the case of emaciated patients, or in obese patients temporarily when the sugar is excessive and does not yield to other measures, I prefer codeine to any other drug. The dose is from  $\frac{3}{8}$  grain to 12 grains or more daily. It is to be given first in small doses, increased until the point of tolerance is reached or improvement is manifest, and then decreased to the smallest dose at which the gain made can be held. Following Sir B. W. Richardson, I give it in solution with hydrogen dioxide, in some such mixture as this:

Codeine phosphate, gr. ii;  
 Alcohol, f3iv;  
 Dilute phosphoric acid, f3ii;  
 Glycerin, f3vi;  
 Solution of hydrogen dioxide (10 volume),  
 enough to make f3iii.  
 Dose.—2 teaspoonfuls in 3 ounces of water.

With this an alkaline course is usually conjoined, the patient being given some suitable mineral-water. Arsenic is sometimes added. Hydrogen dioxide, potassium permanganate, ozonic ether, and oxygen have been advocated on chemical grounds in the treatment of diabetes. I believe that any of them would be useful in helping to avert threatened coma, the special indication, as Harley has shown, being disappearance of sugar from the urine. The theory is simply that they bring about increased oxidation of the sugar or secondary products circulating in the blood. Hydrogen dioxide water can be given in much larger doses than I have mentioned,—almost *ad libitum*, in fact,—and oxygen can be conveniently given by inhalation. Ozonic ether can be injected hypodermically.

I have not spoken of diet, taking that for granted. It precedes medication. I will only say: Don't try to cut off bread and potatoes altogether; the patient won't submit. Gluten bread is not reliable and is not palatable. Give small quantities of ordinary bread,—toasted, if you like,—say six small slices or

three rolls a day. An occasional roasted mealy potato will be a great treat and won't harm the patient. Beyond this; try to make up by fats for the exclusion of starches. It is now possible to give our patients a certain form of sugar. Last year I had before the class a young thin man, then in the hospital, to whom I was giving levulose, or fruit-sugar. Careful chemical analyses of his urine by Dr. Henry Leffmann showed that the urinary sugar did not increase, but actually diminished, while the patient was taking this form of sugar. As you know, levulose, so called because it rotates polarized light to the left, has the same empirical chemical formula as glucose, or, as the latter is called from its action on polarized light, dextrose. The rational formula of the two sugars, however, has been recently shown to be different, and the place of levulose is among the ketone group, while dextrose is placed among the aldehydes. This may account for their different relations to the metabolism of diabetics. Twenty years ago Kuelz, of Marburg, showed that diabetic patients could assimilate levulose and inosite, but only recently has the former been produced as a commercial article. I have used it now for nearly two years, and in some twelve cases of diabetes, and in all it has been assimilated. It is sweet,—not quite so sweet as cane-sugar, but sweet enough to enable our patients to gratify their palates,—and it is useful as a carbohydrate aliment. It turns coffee somewhat black. I give it in quantities of about an ounce a day to lean patients; to stout patients simply as a sweetening.

I am making some observations now with lactose,—milk-sugar. Several patients have taken as much as 4 ounces of milk-sugar in a day without increasing the excretion of sugar in their urine. Others can take but a fraction of this quantity. Philip is one of the patients on whom this observation has been made. He can dispose of about two ounces of lactose daily; four ounces cause an increase of about two ounces in his daily dextrose excretion. As a practical deduction from these clinical experiments, I permit my diabetic patients to drink milk freely.

And now, to conclude, I have three words of advice.

1. Keep your patients warm and protected; cold is their greatest enemy.
2. Examine the urine for organic acids and keep the blood-alkaline.
3. In the matter of diet, be strict enough to diminish polyuria and glycosuria, and, if possible, to secure their disappearance, *provided* you

can at the same time keep the patient comfortable; but under any circumstances *make the patient comfortable*.

### VENESECTION.

BY CHARLES GRANVILLE STONE, M.D.,  
BRIGHTWOOD, D. C.,  
Member of the Association and Medical Society of the  
District of Columbia.

**MR. PRESIDENT AND FELLOW-MEMBERS:**—The subject to which I wish to invite your attention to-night is the use of the lancet in the treatment of modern diseases, as viewed from the stand-point of a conservative practitioner of the science of medicine of to-day. I shall not undertake to interest you, as I might, by a long and varied history of blood-letting, since you may all find that in the books, but to call your thoughtful attention to the need of its use to-day as being greater, if anything, than at any time in the history of the race. We are now confronted by such an army of remedies looking towards the object of meeting and destroying the effects of high temperature in the course of disease, that we may well call a halt and ask ourselves, "Where will all this end?" In the death of our patients in many instances, or the permanent injury of some one of the many organs of their bodies, and in a shortening of the very life we have sought to prolong. I refer here to the many and indiscriminate uses of those medicines known now as antipyretics (formerly as antiphlogistics). Now, I shall make the assertion and defy contradiction, that within the last four years there have been more deaths due to the abuse of the antipyretics than ever occurred in any four years of the abuse of blood-letting. I make this bold assertion to call your minds to the contemplation of the truth as it is seen to-day in the practice of each and every one of you. Now, right here let me say that I believe in the use of many of the so-called antipyretics which are before the profession, but I also see one much safer which has fallen into "innocuous desuetude," without sense or reason, simply because it had been abused by the ignorant and those who, like many at the present day, follow the popular trend of professional thought and practice. I shall endeavor to make it plain to you why the great need of to-day is the return of the use of the lancet. I might safely rest this upon the advice of those great lights of our profession, among whom we have Sir Benjamin W. Richardson, Sir George Humphrey, Mr. Pollock, and a great many other eminent men of the present day, but I

prefer, if I can, to convince you that there is a category of cases which has been the guide of the most honored men of the past and the most brilliant men of to-day, and which should demand of you the use of this most convenient, prompt, and potent antipyretic.

In the discussion of a paper read before the Royal Medical and Chirurgical Society of London, January 27, 1891, by P. H. Pye Smith, we have such men as Stephen Mackenzie, Sir George Humphrey, Dr. Broadbent, Mr. Hulke, Mr. Pollock, and Sir Benjamin Ward Richardson coming out in support of the lancet in the strongest terms. I shall here quote their words upon this subject as uttered upon the occasion. Pye Smith had selected in his paper fifty cases, including the following, under three categories: bronchitis, acute and chronic broncho-pneumonia, lobar pneumonia, miliary tuberculosis, valvular stenosis of the heart, pericarditis, Bright's disease, aneurism, apoplexy, and epilepsy. He took the ground that this remedy is to be used to meet certain indications, not one just adapted for any one such disease. First, cyanosis with distention of the right side of the heart, whether from pulmonary or other obstruction to the circulation; second, the intense pain of aortic aneurism; third, uræmic and prolonged epileptic convulsions. Dr. Stephen Mackenzie opened the discussion by saying, "I advocate its use. I have always been in the habit of bleeding in certain prescribed conditions, especially in the three categories of cases in which the author (Mr. Pye Smith) thought that bleeding was indicated. The first class—that of venous congestions—was the one which best exemplified its advantage. Where the patient was in pressing danger, with distention of the right side of the heart, its value was indisputable. Heart-disease might not be permanently benefited, but in capillary bronchitis it not only afforded all but immediate relief of the great distress, but was decidedly curative in its effects. In pneumonia it gave not so much relief to the disease proper as to the struggling right heart. The difficulty is a temporary one, and if this be tidied over the prospect of recovery was materially enhanced, if not accomplished." Here Dr. Mackenzie gave the following interesting and instructive illustration of the efficacy of bloodletting in pneumonia. He had been called in consultation with Dr. Kibbler to see a case of acute pneumonia in a woman previously strong and healthy. Found her cyanotic, pulse 120, temperature 104° F., with respiration 52. She was stupid, drowsy, and apathetic. He said at once, "The only thing

to be done is to bleed." In this opinion her family physician, Dr. Kibbler, agreed. They drew twenty-six ounces of blood. The temperature at this time was  $104^{\circ}$  F. The next morning it had fallen to  $98.2^{\circ}$  F. In the evening the temperature ran up to  $104^{\circ}$  F. again, pulse 120, and respiration 55. Dr. Kibbler applied a few leeches, which failed to afford any relief. The following evening the patient's condition seemed so desperate (she being unconscious, pulse 130, temperature  $105^{\circ}$  F., and respiration 80) that Dr. Kibbler now drew twelve ounces of blood, with immediate relief to the most urgent symptoms and the temperature falling the next day not to rise again. Dr. Kibbler and his father, who had watched the case narrowly, were strongly of the opinion that the bleeding had been the means of saving her life. He also recalls a case, seen with his brother Lewis Mackenzie, of hæmoptysis. The blood had run down into the trachea and bronchi and the patient appeared in imminent danger. They bled, and he was immediately relieved and ultimately recovered. He says he believes that the iodide of potassium will, when given in large doses (30 grains), afford relief to the pain of aneurism, but it is not so sure nor so prompt as venesection, and he refers to a case, the specimen of which is now in the British Medical Museum, which had been cured by bleeding. Sir George Humphrey related at this meeting several cases wherein bleeding freely had saved the lives of patients beyond a doubt. He says he knew two brothers who had pleurisy. One was bled by him; the other was treated by another physician and was not bled. His case recovered promptly, while the other died. It was his opinion at the time that if the brother who was not bled had been bled, he would have recovered, too. Sir George's experience in bleeding in uræmia had been limited, but it had been attended with good results. He related a case where he had been called in consultation. The patient had bronchitis with albuminuria, and he advised bleeding, but the medical man stood aghast and said he did not bleed nor even know how. Sir George thereupon bled the patient himself. The doctor told him afterwards that he truly believed it saved the man's life. Dr. Broadbent said he had formed a strong prejudice against the practice of bleeding while a student in Paris, because the doctors there bled in cases of typhoid and rheumatic fevers; but that, after leaving the hospitals and becoming an independent practitioner, little by little the advantages of venesection became apparent to him, and for a

long time not a year had passed without him having occasion to recommend it, and he often had to do it himself. He had seen patients' lives saved by bleeding in mitral stenosis and regurgitation, when, the balance having been restored, the patient had gone on for many years. He says, further, "The time to bleed in bronchitis is when you have a strong-beating heart and a feeble pulse, which indicates pulmonary obstruction. Dr. Hulke related a case of a man who had been brought into the hospital with injury of the head, and some time afterwards was taken with convulsions without any premonitions. He was called to his bedside, and found the patient with labored breathing, veins of the head and neck large and distended, and with a purple, congested face. He immediately bled him freely, with instant relief to all the symptoms. The man fell off into a refreshing sleep and was discharged the following day. Mr. Pollock insisted on the importance of bleeding in surgical cases, such as injuries of the head, fractured ribs, perforated lungs with more or less escape of air into the pleural cavity and great distress of breathing, and in hæmoptysis he knew nothing that conduced so much to the comfort and relief of the patient as bleeding. He said he was frequently and painfully mortified at the ignorance shown by the students who came up before him for examination for the army and foreign service; that they neither knew when nor how to bleed. Now, the only man in that great body of great men who could not and would not advocate the use of the lancet was Mr. Jonathan Hutchinson, who said that, as a surgeon, he could not use it, because he was afraid that some one might accuse him of having bled his patient to death. This very clearly shows that Mr. Hutchinson has not been practising that which he thought best, but what was safest for his own reputation. He was willing for them to die without the proper effort on his part to save, rather than run any risk of having his treatment questioned by the profession of popular gentlemen who condemned the same. That forcibly illustrates the condition that exists to-day in our profession in this country, and especially in this our capital city. Professor Samuel D. Gross, long before his death, advocated in his own city and in many others the return of the lancet, and acknowledged that he had, in his best opinion, lost some very eminent men through neglect of the use of that important little instrument. Who here tonight will pause even for a moment to question the truthfulness of this great surgeon's convictions? All of you are more or less indebted to him for what you know about the surgical

practice of medicine, and why should you doubt or question his correctness in this particular? Simply because it is not popular! But I tell you it will be popular long before many of you become too old to practise your art. I wish now to recall the opinion of one whom you all know of, and I doubt not many know personally, as being one of the foremost authorities in this country on the science and practice of medicine, and that reputation has been acquired largely because he is one of the best pathologists and because his opinions are founded upon pathological facts and not mere guesswork. I refer to Dr. William Osler, professor of medicine in the Johns Hopkins University, of Baltimore. He says, when a patient is brought into the hospital in a state of urgent dyspnoea in emphysema, with lividity and great engorgement of the veins, especially if the patient is young and vigorous, he should be bled at once. "I have," he says, "on more than one occasion saved the life of the patient by bleeding freely." In mitral and tricuspid stenosis with great engorgement of the venous system and resultant anasarca, he says bleeding will afford the most prompt relief. He also says that nothing will relieve the pain in aneurism sometimes so promptly as venesection. He likewise employs it in cerebral hemorrhage, effusion of serum, and venous congestion with great arterial tension. I might consume all my time here to-night with quotations from the most brilliant authorities of this country and Europe in support of my previous assertion that there never has been a time in the history of man when this most potent agent in the practice of medicine has been more needed than in this present day; and why? Simply because, as we become more civilized and highly educated, we are becoming more and more the subjects of diseases that are best met and treated by this remedy. We see by statistics that such diseases as congestion of the brain with effusion or hemorrhage have gradually increased, likewise pulmonic obstructions, also liver- and kidney-diseases, all of which are especially amenable to the antiphlogistic or bloodletting treatment of our forefathers. Our mode of life certainly is largely responsible for these conditions, more so than any change in the type of disease or climatic environments. Now, let us see just what we might reasonably expect from this bloodletting treatment, viewed in the light of present biological, physiological, and pathological science. The bacteriologist has certainly proved that our great phlebotomists—Sir Astley Cooper, John Hunter, and John Bell, of England, and

the immortal Rush and Physick, of this country—were right when they claimed that there was a "humor in the blood" which could be bled out to a great extent, at least sufficiently to enable the patient to survive the immediate effects and give other means a chance to perfect a cure. While they did not know what these ferments were, they recognized the fact that by bleeding the patient you drew off a great portion of this poison, whatever it might be, and by the water which the patient required after venesection you diluted the poison which remained in the blood and thus destroyed its immediate virulency upon the human system. Now, we know that these so-called humors or ferments were nothing else than the various bacilli or their toxic ptomaines of to-day. Therefore, where would you find, of all the remedies in the Pharmacopœia, so potent a remedy in the congestive chill of malignant intermittent fever as bloodletting? There is none. You not only relieve at once the overloaded right heart, but you relieve the congested and almost paralyzed brain and spinal cord, which, if not relieved at once in this prompt and easy way, may cost you the life of your patient. Certainly, in these cases you would not think of waiting for the slow action of a purgative or any of the mild revulsives that might be at hand. As I said before, where will you find another means so prompt to relieve your patients of immediate danger? Another condition. Suppose you are called suddenly to see a large plethoric individual who has just fallen to the floor with apoplexy. You see him, like the late Congressman who died here the other day, with gasping breath, eyes turned back in his head, face cyanotic, and with a perfect and total paralysis of the entire body. Now, in this case, what, in the name of a great and good God, can you do with drugs? You can give but one answer to this question truthfully, and that is, Nothing. What might you do with the lancet or your penknife, if you had nothing else better adapted? Bleed him, relieve the overtaxed heart and the engorgement at the base of the brain, and restore him to consciousness, if not to health again, as I have in several instances. I shall relate one instance that just now occurs to me. Several years ago one of our prominent citizens was in the collector's office of the district waiting for the clerk to give him his tax bill, which he wished to pay. He had been quite excited and worried about the amount of the assessment, and had not been feeling well that morning. He had said before going to town that he had a "swimming" in the head. Just as the clerk handed

him the bill he commenced to stagger and speak incoherently, and would have fallen to the floor had he not been caught just in time by some one standing near. They immediately called in a couple of physicians and had him conveyed to the house of one of them, and they applied the popular treatment, of course. This failing to restore him to consciousness, the wife, who had been hastily sent for, telephoned me, and asked me to come down and meet them, that she was bringing him out home in a carriage. I met them half a mile from the city, and turning my horse and buggy over to his son, who had also now joined them, I got in the carriage with my patient. They had him propped up in the carriage with pillows, and he presented the appearance of a dead man, only that his face and forehead were lined with great blue veins that stood out like whip-cords. His breathing was slow and stertorous, while his heart was beating like a sledge-hammer. I hurried the driver, and in less than twenty minutes we arrived at his house. I had him taken to his room, and, after having removed his clothes, tied his left arm and drew about thirty-two ounces of blood. It ran very slowly, and was black and thick at first, but before I had finished it became bright red and natural looking. He became perfectly conscious, and commenced to relate the particulars of the attack and when it had happened, before I had tied up his arm. Now, in this case, I feel assured that bleeding was not only the thing, but the best and only thing to be done. He entirely recovered from this attack, and was free of the slightest signs of paralysis and remained so for a long time after, but had another attack from having violated my injunction that he should give up the habit he had of going over and around his yard and picking up stones or anything that might have been neglectfully thrown there. In the second attack he was not only in strong convulsions when I reached him, but he showed perfect hemiplegia. I again bled and restored him to consciousness, but he could not articulate plainly, nor did he ever entirely regain the use of his limbs on the right side, although he could walk with the assistance of his valet. This condition of things lasted for nearly one year, when he was taken with a third attack, when I declined to bleed him (though the family wished me to) because his condition was not likely to improve over what it had been for the last year. The chances were that the bleeding could not relieve the case, so, taking the advice given by Dr. Hutchinson, I saved myself from being accused of having bled him to death.

I cannot refrain from referring to a case of acute lobar pneumonia which came under my care some twenty years ago, or the second year of my practice in this District. It was late at night and just after a dreadful storm in April; when quite near the house I was confronted with a greatly swollen stream; but as I was contemplating returning and taking the chances that the patient would get along all right until morning, I looked up to the house, which was located some twenty-five yards up the hill on the other side of the stream, and could very distinctly see the father and mother struggling with the young man to keep him from getting out of the window. This settled the matter of fording the stream. I arrived just in time to help them carry him back from the stairway, where he had tried to descend in his effort to escape in his wild delirium. I had great difficulty in keeping him quiet enough to make a physical examination. I found a double pneumonia, both lungs almost entirely solidified. This condition was accompanied by a strong-beating heart, feeble pulse, and a cyanotic face; respiration some 60. I did not attempt to take his temperature, but hastily tied up his left arm and took some thirty ounces of blood. This was immediately followed by perfect quietness of the patient and relief to all of the most urgent symptoms. I then ordered for him some powders containing 8 grains of Dover's and 2 grains of calomel, to be given every three or four hours, as needed to quiet him, knowing that the bowels would move freely from the effects of the calomel, and that he would not likely need another bleeding in the morning. I also had a blister, five by six inches, applied over each lung and then covered by a meal poultice, to be changed every hour until the blisters drew. I remained a couple of hours and then left him sleeping as sweetly as a new-born babe, and returned the next morning to find him perfectly rational, breathing freely, respiration only about 20, cough not troublesome, but raising the prune-juice expectoration with great ease and in great quantities. The temperature was now 102.5° F., and his skin, which had been hot and dry the night before, was moist and felt all but natural. This case made an uneventful recovery, being out at work in less than three weeks. I am perfectly satisfied that if I had not bled him he would have died before I could have got anything else to act. If any one in this Society should doubt the truth of this statement, I will be glad to take him out and introduce him to the family and have the family vouch for all that I have said.

Now, let us look at the subject of bleeding "spring and fall," or, in other words, bleeding as a prophylactic. As I said in the beginning of this paper, there are certain indications as regards youth, strength, and the plethoric condition of the individual which, in the present advanced state of our knowledge of etiology and pathology, must perforce recommend this treatment to us in a number of cases as the best we have at hand. Now, we will take for example one of our active businessmen, who weighs, say from one hundred and eighty to two hundred and twenty pounds, full-blooded, plethoric, with florid complexion, of a bilious habit and lymphatic temperament. He frequently complains of headache and swimming in the head. He is a good liver and takes his grog. This patient, if you will take thirty-two ounces of blood from his arm "spring and fall," will be relieved of those symptoms, and if he be of apoplectic parents you will prolong his life. If he is, as many of these men are, the subject of catarrh of the bowels, he will get well of that ninety-nine times out of a hundred. Now, why would bleeding cure the headache, swimming in the head, and prevent apoplexy? Because the blood is in excess of that required in the economy, and because bleeding will lessen the arterial and venous tension. Now, how will it do this? Simply by a common law of physics. We know that, if we take a thin rubber tube and force fluid through it, the tension is increased in proportion to the density of said fluid,—that molasses would rupture the tube under the same force that would drive water with equal rapidity free of all danger. If the blood of a healthy individual is forced through the arteries under fifty-two pounds' pressure and at a velocity of twenty inches per second without injury to the vessels, molasses in its stead would rupture every artery of the body under the same force and rapidity of stroke. Therefore, when we bleed we thin the blood, because the system will replace in a very short time the loss in quantity by the absorption of water either from that supplied to the patient from without or it will take it up from the serous sacs or cavities from within. I admit that bleeding thins the blood of its solid elements, and, while doing this, removes a large per cent. of that which acts upon the system as the cause of disease. If you inject a large dose of some poison into the blood and immediately bleed freely, and give the patient at the same time large quantities of water to drink, you will so dilute the poison after what you have abstracted through bleeding, that the dose, which would otherwise have killed, will pass harm-

lessly out of the system and your patient will not be any the worse for it. We know that modern science has clearly demonstrated the fact that if we reduce the pressure in the capillaries, we will relieve the heart force or the necessity of it, reducing its work and therefore lessening the danger of heart-failure. This seems so clearly demonstrated in the practice of bloodletting in the prescribed indications in disease, that whether or not we can prove the theory true matters little. I have to-day a lady who lives in the District, and whom I have bled "spring and fall" for the last eight or ten years, and I am certain she would have died long since if it had not been done. There has been a case in my practice within the last twenty years whose blood-making organs were so active that it became a disease or abnormal condition, and who, notwithstanding the most rigid course of diet and exercise, had to be bled twice a year to save his life, on account of the great danger from pulmonic congestion. The father of Mr. Gude, your energetic florist on F Street, was one of these patients to the day of his death, which was caused, as his son will tell you, because he neglected to come when he knew from his feelings that he ought to be bled. This man had been given up to die by two of the most honored men whose names ever adorned the roster of this Society, and yet, as I said before, under the spring and fall bleeding he lived for some eight or nine years. I thank you, gentlemen, for the patient attention which you have accorded me this evening, and sincerely hope that I have convinced some of you of the great therapeutic value of this handy remedy.

#### THE PHYSIOLOGICAL ACTIONS OF ALCOHOL.

ABSTRACT OF A PAPER PRESENTED TO THE SECTION ON THERAPEUTICS OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS, HELD AT WASHINGTON, D. C., SEPTEMBER 5, 6, 7, AND 8, 1893.

BY DAVID CERNA, M.D., PH.D.,

Demonstrator of Physiology and Lecturer on the History of Medicine in the Medical Department of the University of Texas; formerly Demonstrator and Lecturer on Experimental Therapeutics in the University of Pennsylvania; Spanish-speaking Secretary (Section on Therapeutics) of the First Pan-American Medical Congress, etc.

(Continued from page 232.)

**ON THE BLOOD-PRESSURE.**—Following an injection of a small quantity of alcohol in the normal animal, as is observed in the preceding experiments, there occurs within a short time a sufficiently marked rise of the column of mercury in the manometer. After a while the pressure returns to its normal

height, and again rises if a second dose is given, to be once more decreased below the normal if the amount of the drug ingested is carried beyond a certain limit. Thus, in Experiment 10, after the administration of 10 cubic centimetres of a twenty-five-per-cent. solution, a rise of 18 millimetres occurred one minute and forty-five seconds afterwards, and in two and a half minutes more the pressure fell to 158 millimetres (the normal being 154). A second injection of 15 cubic centimetres was followed by an increase of 16 millimetres above the normal point within half a minute. The pressure stayed up for about two minutes. A third injection of 20 cubic centimetres caused a very slight rise, this lasting for about eight minutes, and then there was a gradual fall below the normal. The same results are noticed in Experiments 11 and 12.

In Experiment 13 a continuous injection was employed of a solution of the strength of twenty per cent. Three minutes after the injection had been started the pressure rose to 138 millimetres (the normal being 132 millimetres), and to 142 millimetres three minutes later. By the time that the animal had received 50 cubic centimetres of the alcoholic solution (eight minutes after the beginning of the injection), the pressure marked 138 millimetres, still above the normal; but it soon afterwards began to diminish, and was seen at 128 millimetres by the time that 155 cubic centimetres of the solution had been ingested into the animal. The pressure, with slight variations and accompanied by disturbances of reflexes and respiration, then fell gradually till the occurrence of death, this latter issue taking place through failure of the respiration.

Similar results were obtained in Experiment 14. In this animal the normal pressure was 138 millimetres. There was a slight rise a few minutes after the commencement of the injection. By the time the dog had received about 260 cubic centimetres the column of mercury marked 118 millimetres. The crural nerve, which had been previously prepared, was then stimulated with an electrical current of medium strength, and a few seconds afterwards the pressure rose to 122 millimetres, showing evidently that the vaso-motor system was intact. When 325 cubic centimetres of the alcoholic solution had been ingested the pressure marked only 98 millimetres. At this time the sciatic nerve, which had also been previously prepared, was irritated with a strong faradic current, and the column of mercury in the manometer was seen to rise to 106 millimetres. Ultimately the animal died from respiratory

failure, having lived forty-six minutes under the influence of alcohol.

Experiment 15 shows the same effects on arterial pressure. After 6 cubic centimetres of pure alcohol had been administered, the column of mercury was reduced to 120 millimetres (from 150 millimetres, to which it had been elevated,—that is, 12 millimetres above the normal). At this time artificial asphyxia was produced by tying the trachea tightly. Here, again, under such circumstances, there was a decided response by the vaso-motor system, as shown in the rise of pressure to 142 millimetres.

I found, likewise, that in curarized animals—in which any influence exercised by the respiration on blood-pressure is thus avoided—alcohol, in small amounts, produced the same results, as may be observed in Experiment 17.

Large doses of the drug cause from the onset a decided lowering of the arterial pressure, this decreasing, if the amount has been sufficiently poisonous, till the occurrence of death. If the dose be moderately large, its ingestion into the torrent of the circulation will be followed by a decided fall, the result, no doubt, of an overwhelming action upon the heart. In these instances the pressure is apt to recover, but does not go beyond the normal height.

Let me explain how these changes of blood-pressure are brought about. It has been shown by the most recent physiological researches that when, in an animal under the influence of a drug, the two curves (as registered on the revolving kymograph), one representing the rate of the pulse and the other the height of the blood-pressure, run parallel, such an effect is the result of an action upon the heart; but if opposite to each other, the phenomenon is dependent upon a vaso-motor influence. In other words, if the arterioles are made to contract through a vaso-motor stimulation or spasm, the blood-pressure rises; but, at the same time, the increased pressure stimulates the cardio-inhibitory centres in the medulla oblongata. As a consequence of this latter phenomenon the rate of the pulse falls, and thus the curves of the pressure and the pulse run in opposite directions. When this takes place it is assumed that the change in the arterial pressure is due to a vaso-motor influence exercised on the arterioles.

Now, then, a plot taken from a kymographian record of an animal under the influence of alcohol in moderate amounts would undoubtedly show a parallel course of the curves, this alone giving evidence of a cardiac action. There is, however, further and perhaps more conclusive

evidence of this action of the drug under consideration.

Faradization of a sensitive nerve and asphyxia are able to elevate the arterial pressure depressed by toxic quantities of alcohol, this result proving that the vaso-motor system is intact. But the stimulation by small doses of alcohol might as well be ascribed to an influence exercised on the vaso-motor system or to paralysis of the cardio-inhibitory apparatus as to a direct cardiac action. Yet that such is not the case is shown by the results obtained in the third and fourth series of the experiments performed on dogs. In these experiments the cardio-inhibitory and the vaso-motor influences were eliminated by previous section of both pneumogastric nerves in the first place, and by previous division of both vagi and the spinal cord in the second instance.\*

The results obtained in Experiments 18 and 19 and in 20 and 21 are obvious. An examination of the corresponding tables shows that alcohol, under such circumstances, is still able, when given in small quantities, to stimulate both the arterial pressure and the pulse-rate. Large doses of the drug in all cases produce from the onset depression effects.

It must be concluded, then, from the foregoing experimental evidence, that alcohol in small amounts causes a rise of the arterial pressure by a direct action upon the heart, and that in large or toxic quantities it lowers the blood-pressure similarly through a cardiac influence.

*On the Blood.*—If alcohol is mixed with blood outside of the body, coagulation is enhanced. I have often observed this in my experiments, in those made solely to study this phenomenon as well as in those already sufficiently described. I found that coagulation could be largely avoided by diluting the agent before its ingestion into the torrent of the circulation. To what these effects were due was not determined. Microscopical examination of the blood of animals killed with alcohol showed a marked alteration of the corpuscles, many of these appearing shrivelled and exhibiting yellowish matter in their interior. This latter observation has been previously made by Jaillet and Hayem,† and long before by Schulz.‡ Schmiedeberg§ has noticed that alcohol mixed with blood diminishes the ability of this fluid to yield oxygen in the presence of a reducing

agent. There is no doubt that alcohol in this action causes the separation of the hæmoglobin from the corpuscles.

#### ON THE RESPIRATION.

Small doses of alcohol do not markedly affect the rate of the respiratory movements. In large or toxic amounts the drug generally decreases the respiratory rate, although this is sometimes primarily or secondarily increased, accompanied by a diminution of the depth of the movements. As a rule, the amount of air going through the lungs—whether the rate is increased (in which case the respirations are usually shallow), or whether the depth of the movements is diminished—is decreased. The results of the experiments recorded herewith in regard to the respiratory rate are sufficiently clear. As the same effects are noticed in animals in which the vagi have been previously divided, it is evident that the drug diminishes the respiratory movements by a direct action on the centres in the medulla.

I have found that alcohol not only produces, in sufficient amounts, a decreased rate, but also a diminution in the depth of the respiratory movements, this giving rise to a lower quantity of air passing through the lungs than in normal conditions.

I have in this respect conducted a special series of experiments, the results of which are recorded below.

A simple apparatus was constructed,|| consisting of two bottles filled with mercury, in which this substance served the purpose of a valve against tubes inserted through a tight rubber stopper. Both bottles, by means of rubber tubing and a Y-shaped glass tube, were connected with the trachea of the animal; and, in turn, one of the bottles was left in contact with the atmosphere, the other with large rubber bags, these again being made to communicate with a common air-meter. Thus the air inspired by the animal was wholly transferred to the rubber bags, and the amount of air passing through the lungs in a certain period of time more or less accurately ascertained by the meter. I first measured the air for two or three periods of five minutes' duration each before injecting the drug, and then proceeded to repeat the operation while the animal was under the influence of alcohol.

The same results were obtained in animals in which the vagi had been previously severed. In

\* Post-mortem examination of these latter animals showed that the cord had been completely severed.

† Virchow and Hirsch, *Jahrbucher*, 1884.

‡ *Hufeland's Journ.*, April, 1841.

§ *Virchow's Archiv*, Bd. ii. S. 171.

|| The apparatus was suggested to me by Professor H. C. Wood, while working with him in the laboratories of the University of Pennsylvania.

this connection I have made the observation that, after division of the pneumogastrics, although the respiratory movements, as is well known, are diminished in rate, there is quite often an increase in their depth, and, as a consequence, a larger amount of air than in normal conditions is taken in by the animal. On the other hand, I have frequently noticed that, after section of the vagi, instead of a decrease, there often occurs an enormous increase in respiratory rate; but, at the same time, the shallow character of the movements admits of a proportionate diminished amount of air entering the lungs.

Alcohol, after previous division of the vagi, is still able to produce a diminution in the depth of the respirations, this diminished depth causing a lessening of the quantity of air inspired. The following records show this:

*Experiment 22.—Dog; weight, 7.71 kilos.*

Period.	Respiration per min.	Meter air-movement.	Remarks.
First.....	48	7.9	Dog quiet.
Second.....	46	7.6	Dog quiet.
Third.....	46	7.6	Dog quiet; injected 2 c.c. of pure alcohol.
Fourth.....	36	5.4	
Fifth.....	30	4.9	Dog quiet; injected 1 c.c. of pure alcohol.
Sixth.....	24	4.1	Eye reflexes very weak.
Seventh.....	24	4.1	Respirations shallow.
Eighth.....	24	4.1	Injected 2 c.c. of pure alcohol.
Ninth.....	22	3.8	Eye reflexes gone; animal alcoholized.
Tenth.....	18	3.1	Eventually killed with ether.

*Experiment 23.—Dog; weight, 12.6 kilos.*

Period.	Respiration per min.	Meter air-movement.	Remarks.
First.....	72	19.6	
Second.....	72	19.4	
Third.....	78	20.0	Animal struggles; injected 2 c.c. of pure alcohol.
Fourth.....	60	15.1	
Fifth.....	54	13.0	Injected 3 c.c. of pure alcohol.
Sixth.....	36	9.4	Eye reflexes gone; injected 5 c.c. of pure alcohol.
Seventh.....	30	7.3	Respirations irregular and shallow.
Eighth.....	12	5.7	Muscular rigidity.
Ninth.....	8	4.6	
Tenth.....	6	3.8	Respirations very shallow; killed with ether.

*Experiment 27.—Dog; weight, 10.8 kilos.*

Period.	Respiration per min.	Meter air-movement.	Remarks.
First.....	26	9.3	Alcohol (25 per cent.) used.
Second.....	24	9.5	
Third.....	24	10.0	Cut both vagi; tube in trachea.
Fourth.....	12	11.2	Period taken 10 minutes after cutting of vagi.
Fifth.....	16	12.1	
Sixth.....	12	15.8	Respirations deep.
Seventh.....	12	16.1	Started injection.
Eighth.....	10	12.0	
Ninth.....	8	10.2	Eye reflexes weak; has received 125 c.c.
Tenth.....	8	7.0	
Eleventh...	6	5.1	Has had 200 c.c.
Twelfth.....	6	3.7	Has had 240 c.c.; stopped alcohol.
Thirteenth..	6	2.1	Respirations quite shallow.
Fourteenth	...	...	Animal died.

As in the case of the respiratory rate, alcohol, therefore, causes a depressant effect on the depth of the respiration and the amount of air passing through the lungs, such a result being due also to a direct action of the drug on the respiratory centres in the medulla oblongata.

In concluding this portion of the subject, in which, by the methods sufficiently described, I have been able to study at the same time the behavior of alcohol on the circulation and the respiration, I may state that I did not attempt to ascertain the minimum fatal dose of the drug in dogs. In fact, the action of alcohol upon the lower animals, even of the same species, varies as regards its toxicity, and any general conclusions drawn from one series of experiments may be diametrically opposed to those arrived at in a second series. However, taking into consideration the most striking of my experiments, I obtained the following records: In Experiment 12, 17 cubic centimetres of pure alcohol proved fatal to a dog weighing 9.9 kilos, or 1.7 cubic centimetres per kilo of the body-weight may be said to have been the lethal dose. In Experiment 13, a dog weighing 8.3 kilos died after an injection of 320 cubic centimetres of a twenty-per-cent. solution of alcohol, giving as an average for the fatal amount 38.5 cubic centimetres of the solution per kilo of the body-weight. In Experiment 14, in which a twenty-five-per-cent. solution of alcohol was employed, 325 cubic centimetres of this was sufficient to destroy a dog weighing 8.9 kilos, the average being quite similar to that noticed in the

second example here referred to,—that is, 36.5 cubic centimetres per kilo of the body-weight. Eagleton observed that alcohol in the strength of twenty-five per cent. produced death in the proportion of from 5 to 40 cubic centimetres per kilo of the animal's weight, results apparently somewhat similar to mine.

#### ON BODILY METABOLISM.

*On the Elimination of Carbon Dioxide and the Absorption of Oxygen.*—The absorption of oxygen and the elimination of carbon dioxide have been the subject of very elaborate researches, and although there appears to be some difference of opinion in the two questions at issue, most investigators seem to have arrived at almost definite conclusions. Let me, however, bring to the notice of the reader the most important points in the controversy, which will serve as the basis for this study and for further research. The subject certainly needs to be further investigated.

In regard to the elimination of carbon dioxide, Boecker,\* Perrin,† Davis,‡ Hammond,§ Boeck and Bauer,|| and Rumpf¶ affirm that, under the influence of alcohol, there is a distinct decrease in the amount of carbon dioxide exhaled; and whiskey, brandy, and gin diminished the production of the gas, according to the researches of Smith,\*\* quoted by Wood; †† diminished the production of the gas, it is true, but alcohol in small quantities increased the elimination of the carbon dioxide. This same increase has been observed by Wolfers‡‡ in the case of rabbits.

Closely allied to this question of elimination of carbonic acid is that of the absorption of oxygen, similarly of the greatest interest. This has also been the subject of several investigations. Thus, Henrique,§§ from experiments performed upon himself, found that there was an increase in the amount of oxygen consumed. Identical results were obtained by Wolfers||| in the rabbit, and in rabbits and dogs by Bodländer.¶¶ Zuntz,\*\* who experi-

mented upon man, came to opposite conclusions, asserting that the consumption of the gas is decreased. Forster††† made similar observations. "No important effect," on the other hand, was noted by Geppert‡‡‡ in a similar series of experiments. The matter has been discussed at length by Warren,§§§ and Wood,||||| commenting upon the contradictory nature of the evidence presented up to 1891, states that to his mind such evidence "is probably in part due to the experimental difficulties of the subject, but at the same time strongly indicates that moderate doses of alcoholic spirits have no constant very decided action upon the formation and elimination of carbonic acid. It is readily conceivable that by checking or aiding digestion, by influencing circulation, or in some other way, they may exert a varying indirect action, which is superior to the slight direct influence in lessening carbonic acid production, which the weight of evidence indicates that they possess."

*On Nitrogenous Excretion.*—Upon the elimination of nitrogenous material alcohol has, although denied by some observers, a very decided action. Boecker¶¶¶ has apparently proved experimentally that the drug decreases the elimination of urea. This is denied by Parkes and Wollowicz;\*\*\*\* and yet it is seen in the experiments of these latter investigators that, with the exception of one day in which the man experimented upon had a chill followed by a feverish reaction, the daily excretion of urea was 34.35 grammes during the alcohol period; during the time when brandy was taken the elimination of urea was 34.8 grammes, while during the water period it was 35.02 grammes. There was, therefore, a reduction in the excretion of urea by about 10 grains (.65 gramme) daily. Hammond, quoted by Wood,†††† experimented upon himself, dividing his experiments into three series: First, when just sufficient food was taken to maintain the weight of the body; secondly, when more food than enough was taken for that purpose; and, thirdly, when not enough food was ingested. The results noticed were in all instances similar,—that is, they showed that alcohol lessened the amount of chlorides, phosphates, and urea. These results have been confirmed by the careful experiments of Rieso,†††† made on two persons placed under the strictest conditions. This

author found that, under the influence of alcohol, there was a marked decrease in the urea elimination, and to a less degree also in the excretion of chlorides, phosphates, sulphates, and uric acid. There was at the same time a gain of the bodily weight.

This action of alcohol on metabolic changes is further corroborated by the excellent researches of Mohilansky,\* house physician to the clinic of Manassein. The investigator undertook a series of experiments on fifteen healthy individuals, most of them medical students aged from eighteen to twenty-eight years, his object being to study the action of alcohol not only on the nitrogenous metabolism, but also on the assimilation of proteids and fats. Some of the subjects experimented upon were total abstainers, some were occasional drinkers, while others were habitual alcohol drinkers. The ingestion of the drug varied according to the habit of the individual, and the daily dose administered varied from 60 to 140 cubic centimetres (2 to 5 ounces) of absolute alcohol, or from four small wineglassfuls (rumka) to half a bottle of a forty-per-cent. or forty-two-per-cent. vodka (aquavit). In other words, a sufficient amount was given to produce a slight intoxication, as high spirits and talkativeness, etc. The results of Mohilansky's study are so important that I will transcribe the principal ones. He found: 1. In people habituated to alcohol, when taken in moderate quantities, it distinctly improves the appetite and gives rise to a marked increase in the assimilation of the nitrogenous constituents of food, the average surplus amounting to 2.09 per cent., the maximal to 4.22. (Thus, a patient who had been assimilating 93.10 per cent. of nitrogen, without alcohol, when this drug was added to his dietary, proved to be assimilating 96.07 per cent. of nitrogen.) 2. In habitual total abstainers, however, the assimilation is somewhat diminished, from .28 to .33 per cent. 3. The increased assimilation in the former category must be attributed to a more complete absorption and intensified gastric digestion, which result from a prolonged retention of food in the stomach on the one hand and from increased digestive power and secretion of the gastric juice (Bernard, Kretschy, Richet, Lever, Petit and Semerie, and Gluzinski) on the other. 4. The nitrogenous metabolism or disintegration of proteids almost invariably decreases (this happened in thirteen out of the fifteen cases), the average fall being 8.73 per cent., the maximal 19.42 and the minimal .14. (For example, in a patient in

whom the metamorphosis on non-alcoholic days had amounted to 80.11 per cent., on alcoholic days it fell to 63.78.) The decrease is frequently observed even when small doses are taken, but it is invariable in the case of moderate or medium quantities. There does not, however, exist any strict parallelism between the dose and the amount of the inhibition of the metabolism. 5. The decrease remains still perceptible for some time, even after the alcohol has been discontinued. 6. It is probably dependent upon the drug inhibiting the systematic oxidation processes (Manassein, Schmiedeburg, and Boecker), and, further, upon its changing the blood-pressure, dilating the blood-vessels, retarding the circulation, and depressing the bodily temperature. 7. Alcohol also diminishes somewhat the assimilation of fats, as it was found that there was an increase in the quantity of fatty acids excreted with the fæces.

Although not strictly within the limits of the present essay, the work of Diakonoff† in this respect is worthy of mention. This author undertook a series of experiments on febrile patients, with the purpose of ascertaining the effects of alcohol on the assimilation and metabolism of proteids. Of the seven patients experimented upon, six were suffering from typhoid fever and one from exudative pleurisy. Of these patients, two were total abstainers and five occasional alcohol drinkers. The drug was administered internally, in the form of a forty-per-cent. vodka (aquavit), four times a day, the daily dose being invariably 50 cubic centimetres (1½ ounces) of absolute alcohol. The diet of the patients was limited to milk and bread, and the treatment was purely expectant. The author obtained the following results: 1. In febrile patients alcohol lowered the assimilation of the nitrogenous ingredients of food. 2. In regard to this effect of alcohol no difference was noticed between habituated and non-habituated individuals. 3. Alcohol spoils appetite and increases both the total daily amount of fæces and the proportion of water and coagulated albumin therein. 4. The drug decreases the quantity of albumin undergoing decomposition in the system. 5. In such cases, where the assimilation of nitrogen sinks but slightly, alcohol lowers the nitrogenous metabolism; where the depression, however, of the assimilation is considerable, the metamorphosis proves to be augmented. 6. Alcohol disturbs the metabolism also inqualitatively, since it raises the proportion of under-oxidized products.

\* *Medical Chronicle*, November, 1889.

† *Medical Chronicle*, January, 1890.

I have not had a sufficient opportunity to make a study of this part of the subject, but it seems to me, from the experimental evidence brought forward, that this points to a well-sustained conclusion in regard to the actions of alcohol on metabolism,—that is, that the drug produces a decided lessening in the excretion of the products of tissue-waste, both in health and disease.

#### ON ANIMAL HEAT FUNCTIONS.

*On Normal Temperature.*—Alcohol affects the animal heat functions in both man and the lower animals proportionately in a similar manner. Under the action of moderate doses there is frequently produced a slight elevation of the temperature corresponding with a stimulating effect upon the circulation. In other words, the rise of the temperature occurs *pari passu* with an increase of the blood-pressure above the normal point. The following record is sufficiently clear:

*Experiment 28.*—Dog; weight, 15.2 kilos.

Time. min. sec.	Pressure. mm.	Rectal temperature. C. scale.	Remarks.
			Pure alcohol used.
0.00	138	40.0	
2.30	138	40.0	Injected 1 c.c. of drug.
3.00	140	40.0	Injection ended.
5.00	144	40.1	
9.00	148	40.2	
14.00	150	40.4	
19.00	150	40.6	Animal restless.
24.00	158	40.8	Dog quiet again.
39.00	150	40.6	
49.00	142	40.4	
59.00	142	40.0	Killed with ether.

This rise of temperature is comparatively of short duration and apparently unimportant, since subsequently it is followed by a depression below normal, especially when larger and toxic amounts of alcohol are ingested. The results of the preceding experiments on temperature are confirmatory of those observed by Richardson\* and by Parkes and Wollowicz.† The latter authors found a trifling exaltation of temperature after doses sufficiently large to increase the activity of the circulation. Richardson noticed that in minute quantities alcohol increased the temperature in mammals .5° F. and in birds 1° F. above the normal.

It has been sufficiently proved that alcohol in large and lethal amounts produces in animals a fall of the bodily temperature. Even as far back as 1848, Dumeril and Demarquay, quoted by Wood, affirmed that alcohol in large

doses causes a marked decrease of the temperature. The truth of this statement has been more recently upheld by the results obtained in the laboratory and in the clinical ward by a host of able observers. I will not burden the reader with an account of each one of these observations, but I believe it will be sufficient for me to refer to the authorities consulted by simply mentioning them. Almost all experimenters are in accord in regard to the action of alcohol on normal temperature, and the names of Anstie,† Binz,§ Bouvier,|| Brown-Séquard,¶ Davis,\*\* Godfrin,†† Jacobi,‡‡ Lewin,§§ Lombard,|||| Mainzer,¶¶ Manassein,\*\*\* Obernier,††† Rabou,‡‡‡ Raziejewski,§§§ Ringer and Rickards,||||| Ruge,¶¶¶ Sulzyski,\*\*\*\* and Tscheschichin†††† may be recalled.

In the experiment that follows,—an example of others performed,—in which toxic amounts were employed, the depression of the temperature, with slight variations, was quite marked. I may here state that, if the dose ingested is fatal, the fall observed is progressive till the occurrence of death.

*Experiment 30.*—Dog; weight, 9.97 kilos.

Time. min. sec.	Pressure. mm.	Rectal temperature. C. scale.	Remarks.
			Pure alcohol used.
0.00	166	39.3	
3.30	166	39.3	Injected 5 c.c. of drug.
4.00	166	39.3	Injection ended.
5.30	162	39.3	
8.30	152	39.2	Injected 10 c.c. of drug.
9.00	150	39.2	Injection ended.
15.00	142	39.0	Injected 10 c.c. of drug.
15.30	140	39.0	Injection ended.

Time. min. sec.	Pressure. mm.	Rectal temperature. C. scale.	Remarks.
16.00	135	39.0	Animal struggles.
21.00	132	38.8	Injected 10 c.c. of drug.
21.30	130	38.8	Injection ended.
26.30	120	38.6	Dog quiet; eye re- flexes weak.
31.30	112	38.4	Clot for 5 minutes.
37.00	108	38.3	
42.00	98	38.2	Eventually killed with ether.

It is thus demonstrated beyond doubt that alcohol in sufficiently large quantities diminishes the bodily temperature in the lower animals the same as it does in man.

This action, however, is not the same in the case of abstainers and of habitual drinkers. In the first class of individuals the depressing influence is usually produced, but in those persons addicted to the habitual use of alcoholic stimulants the effect is either slight or totally wanting. This is an almost every-day observation. In this respect I may call attention to the elaborate research of Riegel,\* who performed eighty-six experiments on man, with the object of studying the behavior of the drug on bodily temperature. He found that alcohol, even in moderate doses, in many cases causes a lowering of the temperature of the body, the amount of this diminution averaging, as a rule, only some tenths of a degree; that only exceptionally is there noticed an elevation of the temperature consequent upon the administration of alcohol, and that not infrequently, at least after minute doses, there is no noticeable change; that the diminution of temperature in convalescents is, as a rule, less than in healthy subjects, or it may altogether be absent; that in those who habitually drink alcoholic stimulants the depressing influence of the drug upon the temperature is almost always wanting; that frequent repetition of the doses of alcohol diminishes their lowering effect upon the temperature; that the amount of diminution of temperature is directly proportional to the dose of alcohol ingested; and that, finally, the depression of temperature caused by alcohol is for the most part of but short duration, and the temperature soon returns to its previous grade. These statements are in accord with the results obtained by most investigators, as well as with those of my own experiments, and they may, therefore, be said to be entirely correct.

Although the action of alcohol on thermogenesis may be said to be an indirect one, judging from the light of modern research,

it would be interesting to ascertain, if possible, how these heat phenomena are brought about. Here I may say that the deductions of Binz† must be laid aside as of no great value on the basis of recent elaborate researches.

The first calorimetrical studies regarding the actions of alcohol were made by Lewis‡ on rabbits. The author found that the drug sometimes produced a primary decrease of heat production, especially after small doses, followed, under the influence of large quantities, by an increase in the same phenomenon. Later, Wood and Reichert,§ who experimented on dogs, found varying results in five experiments, although in some of these heat dissipation kept in advance of the heat production, and, as a consequence, the temperature was lowered. Sometimes, however, the heat production was above the dissipation, resulting, in such instances, in a rise of the bodily temperature. The subject has been further investigated recently by Reichert.|| The able and thorough research of this author is based upon eighteen experiments performed on dogs, using the ordinary calorimeter described by him.¶ Reichert obtained increased heat production in five and decreased heat production in thirteen of the experiments. The difference did not depend upon the size of the dose employed. The range of variation in the general results was as much as sixty-five per cent. He determined, however, that alcohol does not affect the total quantity of heat produced; that the fall of the bodily temperature is due to the excess of dissipation and is in direct proportion to such dissipation. He infers, therefore, that in all likelihood, alcohol, by undergoing oxidation, yields energy in the form of heat, thus conserving the tissues and acting as a food. The question, nevertheless, cannot be considered definitely settled, and further experimentation in this respect is still wanting in order to reconcile, if possible, all beliefs. The results of Reichert, however, carry the weight of authority, and may be said to be correct in the present state of our knowledge of this interesting part of the subject.

*On Febrile Temperature.*—That alcohol exercises a depressing influence on febrile temperature, both in man and the lower animals, there can be no doubt. Thus, Bouvier\*\* has

|| THERAPEUTIC GAZETTE, February, 1890.

¶ *University Medical Magazine*, January, 1890.

\*\* *Loc. cit.*

noticed that the drug exerts a marked antipyretic action in animals laboring under pyæmic fever. Alcohol in such cases diminished the temperature as much as  $8.5^{\circ}$  C. ! and it was further found that the fever could be prevented if the alcohol was pushed before the appearance of the pathological condition.

The same results have been observed by Ringer and Rickards\* in the case of man, but these authors assert that large and perhaps toxic doses of alcohol have to be ingested before the antipyretic effects occur. As observed by Bouvier,† Riegel,‡ and others, alcohol, even in large amounts, fails to affect the temperature in individuals accustomed to the use of the drug.

There can be no question that alcohol is able to reduce febrile, as it does normal, temperature both in the case of man and the lower animals. In the first instance the action is sustained by clinical observations, and in the second by experimental evidence. I myself have verified this antipyretic action of alcohol. To do this a feverish condition in dogs was produced by the administration of putrid blood.

Two days were employed in each experiment. During the first day it was ascertained only whether the specimen of blood used was sufficiently powerful to produce fever without causing other marked disturbances. During the second day the fever-producing agent and the alcohol were given to the animal at the same time. It was found, then, that the alcohol not only kept the temperature from rising, but even reduced it below the normal standard, these changes depending more or less upon the amount of alcohol ingested. It will be sufficient for me to detail the following experiment:

*Experiment 32.—Dog; weight, 20.12 kilos.*

#### FIRST DAY.

##### *In the Normal State.*

Time.	Temperature. C. scale.
First hour.....	$39.4^{\circ}$
Second hour.....	$39.4^{\circ}$
Injected 5 drops of putrid blood.	

##### *In the Fever State.*

End of first hour.....	$40.5^{\circ}$
Injected 5 drops of putrid blood.	
End of second hour.....	$41.5^{\circ}$
Injected 5 drops of putrid blood.	
End of third hour.....	$41.8^{\circ}$

\* *Loc. cit.*

† *Loc. cit.*

‡ *Loc. cit.*

#### SECOND DAY.

*Dog reduced to 10 kilos.*

Time.	Temperature. C. scale.
First hour.....	$39.6^{\circ}$
Injected 5 drops of putrid blood and 5 c.c. of alcohol, repeating the latter every ten minutes.	
End of second hour.....	$39.6^{\circ}$
Injected 5 drops of putrid blood and the alcohol as before.	
End of third hour.....	$39.6^{\circ}$
Injected 5 drops of putrid blood and the alcohol as before.	
End of fourth hour.....	$39.0^{\circ}$
End of fifth hour.....	$38.3^{\circ}$
End of sixth hour.....	$38.8^{\circ}$

Other experiments gave identical results. The evidence, therefore, is conclusive.

(To be concluded.)

#### STATUS OF THE HYPODERMIC USE OF MERCURIALS IN THE TREATMENT OF SYPHILIS.

READ BEFORE THE PHILADELPHIA COUNTY MEDICAL SOCIETY, APRIL 25, 1894.

BY L. WOLFF, M.D.,

Clinical Professor of Medicine, Women's Medical College of Pennsylvania; Physician to the German Hospital of Philadelphia, etc.

A YEAR ago I read at a meeting of this Society a communication on the subject of hypodermic medication in syphilis, which I prefaced with the remark that "among the therapeutic methods which are largely employed on the continent of Europe, but have found very few adherents in this country, is, no doubt, the 'hypodermic treatment of syphilis.'" This part of my paper seems to have been one of the points that was principally attacked in the discussion following it, as well as in a subsequent classical paper by Dr. J. W. White on "The Present Position of the Hypodermic Treatment of Syphilis." While in this last-mentioned article Dr. White quoted the opinion of some thirty-two American dermatologists and syphilographers, only three expressed themselves favorable to this method; the others state themselves more or less opposed to it. He also states that in Germany some of the best men have pronounced against it, and in France Fournier, also Hutchinson in Great Britain, arrayed themselves against its use. In quoting Fournier, the rather feeble argument is brought forward that he feared the method would cause a rapid disappearance of patients while producing possibly a rapid disappearance of the disease.

One of the arguments advanced against this treatment as practised by me was its short duration, twenty-five or thirty injections being only given, as a rule. To impute that I stopped treatment after this, as has been stated, is to misquote me, as I distinctly recommended in my paper the internal use of iodides for some months thereafter. Relapses may require, moreover, further series of injections, as this is practised in all the so-called opportunists' methods for the treatment of syphilis. To say that, if the curative effects of mercury could be obtained in such a short period and with such small quantities, mercury must have some virtue when given in this way which it does not possess when administered by other methods, is partly true. No one will presume that, of the many ounces of mercury given during the internal treatment for years, all of it will be absorbed and become thereby the truly medicating quantity. Whoever has noticed the gastric and intestinal disturbances created by the mercurials, together with the colitis and even bloody diarrhoeas caused by it, cannot for one moment doubt that much more of the mercury, so ingested, proves of greater danger to the gastro-intestinal tract than of benefit to the syphilis process. Besides all this, the perhaps universally-granted method of achieving the best and most lasting results—*i.e.*, the method by mercurial inunctions—rarely extends over thirty to thirty-five days, and it would appear, therefore, that, arguing from the same stand-point, mercury by inunction acquired the same mysterious curative virtues that have been so sceptically referred to as pertaining to the injection method. It is scarcely within the province of this article to take up the much-argued question of the superiority of the continuous and intermittent prophylactic method of medication over the expectant symptomatic one of the opportunists. I would merely refer in connection therewith to an article by Professor E. Lang, in which he criticises Professor Fournier's statistics of the relations of tertiary symptoms to the duration of treatment, and where he states, after analysis of the tables of Professor Fournier, that, so far from exerting a favorable influence in cases of syphilis, the method of prolonged treatment recommended by Professor Fournier is apt to produce a deleterious effect on the patient's general health by giving rise to various alimentary troubles associated with insomnia and other nervous symptoms of a somewhat grave description and favoring the occurrence of tertiary manifestations. For example, the statistics communicated by Professor Fournier to the First International Congress of Dermatology in

1889 show that the liability to tertiary manifestations increased in his patients until the third year after infection, a fact which is in direct opposition to the experience of the advocates of the opportunists' method, who have never met with the same liability to tertiary accidents during the first three years after infection in the patients under their observation (*Med. Week*, vol. i., No. 47). In the same manner Kaposi (*Wiener Med. Wochenschrift*, No. 4, 1894) expresses himself as opposed to the continuous treatment, which has been so strongly recommended by numerous syphilologists. He considers it as both morally and physically disadvantageous, and thinks the first treatment should be long and carefully executed. The treatment is to be repeated only when true syphilitic manifestations present themselves again. For this purpose mercurial inunctions should be considered first of all, and, where these are impracticable, injections should be next in order. The hypodermic method is eminently an expectant symptomatic one, and the divided opinions on the subject of continuous and intermittent prophylactic treatment *versus* that of the opportunists, by such authorities as just quoted, must also apply in principle to it.

It is to be conceded, therefore, that the objections to the hypodermic treatment are not alone those applying to this method of mercurialization, but one also of school,—*i.e.*, to the periodic treatment in the order as the re-appearance of symptoms requires it. As perhaps a compromise between the continuous and intermittent treatment, Edward Cotterell, in his monograph on "Syphilis: Its Treatment by Intramuscular Injections of Soluble Mercurial Salts" (London, John Bale & Sons, 1893), recommends the intramuscular injections of the sozoiiodolate of mercury, which he uses in the doses of about  $\frac{1}{4}$  grain dissolved in iodide of sodium, once a week for about six or seven weeks, or until all skin and throat manifestations have disappeared, when once a fortnight will be found sufficient for another three or four months, and after this once a month for at least eighteen months to two years or longer, as circumstances may require. What such medication of about one-quarter of a grain of this salt, which contains about one-third of its weight or less of mercury, once a month can accomplish in its influence over the syphilis process is not obvious, and, after all, the effect of the treatment, the results of which he praises so highly, must depend on the massive injections during its first period.

As our methods of treatment are modelled

largely by the teachings of our schools, and as these latter in this country are greatly influenced by the literature of the English-speaking mother country, it is not astonishing that our practitioners should follow the teachings of Hutchinson and the practices of Fournier.

In Continental Europe the two predominating nationalities in medical education are those of France and Germany, and as independent medical centres their doctrines diverge often as greatly as their languages. Thus, the great centre for teaching syphilology in German-speaking Europe has always been Vienna, with its great and magnificent Allgemeines Krankenhaus, whence for many years the teachings of Sigmund, Zeissl, Hebra, Kaposi, Neumann, and others have formulated the doctrines which dominated the German-speaking practitioners.

In view of this, and with the object of presenting a consensus of opinions, not alone of one country and one school, but of the leading minds occupied with syphilology in the principal medical centres of the world, I have undertaken to obtain from most of the teachers of this branch of medical science an expression of opinion in regard to this subject, and in response to my inquiries I have the pleasure to acknowledge the receipt of forty-four letters, all from men well known both as authors and teachers on this subject in the principal universities of Europe.

I first thought it necessary to ascertain if they employed the hypodermic method, for I cannot consider that any one can speak of its merits without experience. I further on desired to know the respective mercurial employed by them in this way, as much might be learned as to the utility of some particular one. Whether among these the soluble or insoluble ones are preferred I also tried to ascertain. Again, I considered it of importance to learn which was thought the most rapid in action and the most permanent in effect. To know if the method was employed in general or in isolated instances only seemed to me an important item in connection with the weight that the correspondent's opinion might carry. While the period of treatment by the hypodermic method seems generally conceded, an individual expression of opinion on this point was also solicited. The disadvantages and untoward effects of this treatment have been made use of so much as an objection to its employment, that I further begged for the experience of the individual observers in this respect. It seemed but proper, also, to ascertain if, in their opinion, the methods were well established or had an ephem-

eral existence only. The question whether this method should be continued or abandoned as a regular treatment for syphilis might with justice be asked of those who had experience with it; and, lastly and principally, it occurred to me to elicit what relation this treatment bore to the time-honored oral ingestion of the drug, and whether the correspondent considered the hypodermic method had largely superseded the administration of mercury by the mouth in the treatment of syphilis. While in these ten queries I endeavored to elicit the opinion of my correspondents, I also asked that such general remarks should be added as might be thought necessary and not covered by my questions.

Before entering upon the responses obtained to my questions, I should mention the names and titles of the gentlemen who have so kindly favored me with their answers.

Those from Vienna are the Professors of Dermatology and Syphilology, Kaposi, Neumann, Lang, and Hans von Hebra, whose clinics for syphilis and dermatology at the Allgemeines Krankenhaus are known the world over; the Docents of Dermatology and Syphilis at the Vienna University, Drs. G. Riehl, Franz Mraceck, E. Kohn, and Max. von Zeissl; from Prague, the Professors of Dermatology and Syphilis at the University there, F. J. Pick and V. Janovsky; from Budapest, Professor of Dermatology and Syphilis, E. Schwimmer, and the Docent for the same branches, Dr. Havas; also Dr. Alex. Zarewicz, Docent at the University of Krakau; from Berlin, Professor Dr. O. Lassar, Professor Schweninger, and his assistant Dr. Buzzi, also Dr. J. Behrend; from Königsberg, Professor Caspary; from Bonn, Privy Medical Councillor Professor Dr. Doutrelepon; from Munich, Dr. Kopp, Docent at the University; from Helsingfors, Russian Finland, Professor Dr. George Smirnoff; from Kieff, Russia, Ord. Professor and Councillor of State Dr. M. Stoukovenkoff; from the St. Petersburg Military Medical Academy, Professor A. Polotebnov; from Charkow, Russia, Professor Brouen; from Amsterdam, Professor D. Van Haren Noman; from Florence, Italy, Professor Celso Pellizzari; from Genoa, Professor Roberto Campana; from Padua, Professor Achille Breda; from Bologna, Emerit. Professor Pietro Gamberini; from Pavia, Professor Angelo Scarenzio; from Catania, Professor Priano Ferrari; from Siena, Professor Domenico Barduzzi; from Lille, France, Professor I. Leloir; from the Military Medical Academy of France, Professor Dr. T. Poncet; from Geneva, Switzerland, Dr. H. Oltramare; from Berne, Dr.

Adolf von Ins, Docent at the University; from Edinburgh, Dr. Ed. Allan Jamieson; from London, Drs. H. Radcliffe Crocker, also S. Mackenzie and Ad. Saugster; from Glasgow, Professor McCall Anderson; from Brussels, Belgium, Professor Dr. Thiery, and from Gaud, Dr. Cruyl, chief of the Dermatological and Syphilitic Division of the Civil Hospital there; also, from this country, Dr. J. C. Wilson, Professor of the Practice of Medicine at the Jefferson Medical College, who was one of the first to use the calomel injections here.

It must be acknowledged that my correspondents represent the principal centres of learning in Europe, that they are all teachers of renown, and they must therefore truly picture the practices of those countries. It can hardly be said of them, as has been stated of the adherents of the hypodermic method, that they are therapeutic enthusiasts, or that they have been selected for the purpose of glorifying this treatment.

In answer to my first question, "Do you employ the hypodermic treatment for syphilis?" the answers are as follows:

Yes, by Kaposi, Neumann, Riehl, Mraceck, Kohn, Zeissl, Pick, Janovsky, Schwimmer, Havas, Lassar, Doutrelepon, Kopp, Brouen, Pellizzari, Breda, Baruzzi, and Wilson; very often,—Lang, Finger; as a rule,—Hebra; with predilection in private and clinical practice,—Schwimmer; in private practice rarely, in hospital practice almost exclusively,—Zarewicz; yes, but not exclusively,—Schweninger; yes, with preference,—Caspary, also Smirnoff; exclusively,—Stoukovenkoff; almost exclusively, with exception of cases of great hyperæsthesia, as in nervous diseases and brain syphilis,—Polotebnoff; yes, but not exclusively; in all cases of beginning secondary, excepting in pregnancy,—Noman; for some years intramuscular injections in preference to subcutaneous,—Gamberini; the benefits of the hypodermic method cannot be excluded from the treatment of diseases of an infectious nature,—Scarenzio; ordinarily,—Ferrari; yes, but not in all cases,—Leloir; yes, I have employed it, but I will employ it hereafter only in exceptional cases,—Poncet; only rarely now, after having had most disagreeable experience with insoluble preparations,—Von Ins; yes, very often, especially if I have the patient under my own eye, or if I wish a very rapid result,—McCall Anderson; yes, in grave cases, and more often in hospital than in private practice,—Cruyl; I use only inunctions in hospital practice, and can therefore say nothing regarding hypodermic injections,—Behrend; I find it impossible to an-

swer the questions in brief, but have always been an enthusiastic supporter of the hypodermic method, and refer for further information to my book, which I send along,—Roberto Campana; employed it so little that I cannot possibly answer the questions,—Oltramare; no,—Jamieson, Crocker, Mackenzie, and Saugster; do not employ it,—Thiery.

As a *résumé* of the answers to the first question, we can say that thirty-six of the correspondents have used and use the hypodermic treatment in syphilis, while one does not answer the questions categorically, but refers to his writings on the subject, and seven acknowledge that they have not used or do not use the treatment, and these cannot, therefore, be considered in the answers to the future questions.

To the second question, "Which of the mercurials do you principally employ?" I have the following answers:

Corrosive sublimate (five per cent.), one injection every week (.05), five to eight injections in all, method introduced by my former assistant, Professor Lukasiwicz,—Kaposi; sublimate, calomel, soziodolate, and peptonate of mercury,—Neumann; I use almost all known preparations,—Lang; sublimate and bichloride,—Riehl; for subcutaneous, sublimate (1 to 100); for intramuscular, salicylate,—Finger; sublimate with chloride of sodium,—Mraceck; sublimate,—Hebra; sublimate (.1 to 20),—Kohn; sublimate, albuminate, and formamidate,—Zeissl; salicylate,—Pick; salicylate, thymol acetate, calomel, and soziodolate,—Janovsky; since two years generally soziodolate, and sublimate for more than ten years,—Schwimmer; gray oil, sublimate, and calomel,—Havas; yellow oxide and, of late, gray oil,—Zarewicz; sublimate,—Lassar; calomel and salicylate,—Schweninger; sublimate,—Caspary; in general, salicylate,—Doutrelepon; insoluble mercurials,—Kopp; in the clinic for the purpose of instruction, insoluble mercurials, also sublimate; in private practice only calomel,—Smirnoff; benzoate of mercury, as introduced by me,—Stoukovenkoff; formamidate,—Polotebnoff; salicylate,—Brouen; sublimate, calomel, gray oil, yellow oxide, salicylate, thymol acetate,—Noman; calomel, sublimate, double iodide of mercury, and sodium,—Pellizzari; sublimate, calomel, yellow oxide, salicylate,—Breda; sublimate,—Gamberini; calomel in vaseline oil,—Barduzzi; sublimate exclusively,—Leloir; calomel,—Poncet; salicylate,—Von Ins; bichloride,—McCall Anderson; sublimate in olive oil,—Cruyl; calomel,—Wilson.

A summary of the answers to the second

question would show that almost all the preparations of mercury generally employed for hypodermic medication are used by my correspondents, some only using one, others a few, while others, again, seem to use all the preparations more or less. The ratio in which the different preparations are used by them, as elicited by my answers, are: sublimate by 22 of the 36; calomel, 14; salicylate, 12; yellow oxide, 6; sozoiolate, 4; gray oil, 4; formamide and peptonate, also thymol acetate, each 2; while albuminate, cyanate, benzoate, and the double iodide were each employed by one out of the 36.

The inference to be drawn herefrom is that, after all, the corrosive sublimate seems to be most general in use for this purpose, with calomel next, salicylate following; yellow oxide, sozoiolate, and gray oil, with the others more rarely used, gradually showing a decrease in their general employment.

While this does not show the individual preference of the different observers for soluble or insoluble preparations, the third question, "Which do you prefer, the soluble or insoluble mercurials?" was intended to bring out the preference, if any, for either of these two classes.

The answers are as follows: Soluble, Kaposi, Neumann, Riehl, Mraceck, Hebra, Kohn, Zeissl, Schwimmer, Lassar, Caspary, Stoukovenkoff, Polotebnoff, Breda, Gamberini, Ferrari, Barduzzi, Leloir, Von Ins, McCall Anderson, and Cruyl.

The insoluble mercurials are preferred by Wilson, Poncet, Scarenzio, Noman, Brouen, Smirnoff, Kopp, Doutrelepont, Havas, Janovsky, and Pick; depends on indications,—Lang; uses both,—Finger; prefers insoluble, but uses the organic soluble where indicated,—Zarewicz; undecided,—Schweninger; as per indications, soluble and insoluble,—Pellizzari.

It would appear therefrom that the preference for the soluble mercurial for hypodermic use is very decided, being indicated by twenty, while eleven state their preference for the insoluble preparations, one is undecided, two give no preference for either, and are governed by indications, while two declare they have no preference.

My fourth question, "Which, in your opinion, is the most rapid in action and the most permanent in effect?" seems to have been the most difficult to answer, and the responses obtained from my correspondents are in this instance not as direct as might be desirable. Thus, Kaposi states it different in every case, and says it cannot be answered in a general

way; soluble,—Neumann; refers to publications,—Lang; soluble preparations perhaps equal in effect,—Riehl; insoluble preparations more energetic than soluble, effect more permanent,—Mraceck; soluble less energetic, less permanent,—Finger; sublimate,—Kohn; most rapid, calomel; saw relapses after all preparations; cannot prefer on that account,—Zeissl; cannot say that the other insoluble preparations are better in this respect,—Pick; calomel; but injections are painful, followed by infiltrations, notwithstanding vigorous antiseptics,—Janovsky; no difference with any of them,—Schwimmer; the soluble are more rapid, the insoluble more permanent,—Havas; yellow oxide and calomel; has not been able to satisfy himself as to the rapid and eminent action of salicylate,—Zarewicz; no real difference in action or in permanency in the different preparations,—Lassar; besides inunctions, salicylate,—Schweninger; probably calomel, which, after bad experience, I do not use any more,—Caspary; a great difference cannot be observed; also refers to literature from the clinic of Bonn,—Doutrelepont; rapidity of action, sublimate with chloride of sodium; permanency in effect, calomel,—Kopp; calomel and gray oil, the latter somewhat dangerous on account of the irregular absorption,—Smirnoff; the soluble mercurials, preferably those that do not coagulate albumin,—Stoukovenkoff; does not depend on the preparations, but on the individuality of the patient,—Polotebnoff; insolubles,—Brouen; yellow oxide and thymol acetate,—Noman; calomel,—Pellizzari; calomel is most rapid and durable in action,—Breda; sublimate more beneficial than calomel,—Gamberini; calomel gives the most prompt benefits, but all mercurials have about equal value,—Scarenzio; sublimate,—Ferrari; soluble,—Barduzzi; no answer,—Leloir; calomel,—Poncet; inunction,—Von Ins; never uses any other preparation than sublimate,—McCall Anderson; sublimate,—Cruyl; calomel is less rapid, but apparently more permanent,—Wilson.

The answers to this question are perhaps the least satisfactory of all, as they show seven of indirect, or rather of indefinite, character. The preference for rapidity in action and permanence in effect is given to calomel by nine of the correspondents, while two declare sublimate more rapid and calomel more permanent in effect. Six speak in favor of the soluble and five of the insoluble, five regard sublimate superior, while two endorse yellow oxide in this respect, and one each salicylate, gray oil, and thymol acetate.

My fifth question, "Do you employ the hypodermic method as a general treatment for syphilis?" is answered as follows:

Yes,—Kaposi, Kohn, Pick, Schweninger, Doutrelepont, Stoukovenkoff, Noman, Barduzzi, Cruyl, and Wilson; in some cases one can only apply the hypodermic method,—Neumann; gray oil in doses of .03 to .04 metallic mercury,—Lang; no, I prefer as first treatment inunctions,—Riehl; no answer,—Finger; only in proper cases,—Mraceck; generally,—Hebra; as a rule, inunctions; injections when these cannot be made,—Zeissl; yes, but as a secondary treatment after inunctions,—Janovsky; in my clinic nearly as the unique application of mercury, but also often inunctions,—Schwimmer; in exceptional cases only, as I can always get along with inunctions,—Havas; in my opinion, injections are most suitable and surest in hospital practice, otherwise the treatment is to be individualized,—Zarewicz; yes, besides inunctions principally in out-door patients,—Lassar; at least often,—Caspary; indeed,—Kopp; yes, decidedly as the principal method, excepting in tuberculosis, cancer, alcoholism, and non-syphilitic cachexia,—Smirnoff; usually,—Polotebnoff; as a general treatment,—Brouen; no,—Pellizzari; yes, in certain minor cases, especially with regard to clinical patients,—Breda; I do not use them in general; intramuscular injections as the prevalent treatment,—Gamberini; I prefer the hypodermic method as more simple and because it does not derange the stomach, also because the dosage can be more accurately regulated,—Scarenzio; the hypodermic method is by me ordinarily used,—Ferrari; no,—Leloir; no,—Poncet; formerly more, now only occasionally,—Von Ins; only as such,—McCall Anderson.

We see, therefore, from the answers to this question, that twenty-six responses indicate the general employment of injections as a treatment for syphilis, while one of the correspondents omits the answer to the question, and four answer in an indefinite and indirect manner, leaving inferences open therefrom, and five distinctly state that they do not generally employ it as a treatment for syphilis.

My sixth question, "What length of time do you continue the hypodermic treatment in the average case?" has brought the following answers:

Six to eight weeks,—Kaposi; soluble twenty-five days,—Neumann; gray oil, once in intervals from three to four days, and with beginning retrograde change once in five, seven, or fourteen days; altogether eight, ten, or twelve such doses,—Lang; twenty to forty

injections and more in relapses,—Riehl; no answer,—Finger; until the disappearances of the existing manifestations,—Mraceck; on an average three to five weeks, in rare cases very much longer,—Hebra; up to three months, unless abscesses or painful infiltrations prevent continuation,—Kohn; until the manifestations of syphilis have entirely disappeared,—Zeissl; indefinite answer,—Pick; till the disappearance of the symptoms,—Janovsky; ten to twelve of sozoiodolate and of salicylate, twenty to fifty sublimate, twenty-five to thirty-five of formamidate, one and a half to two months on an average,—Schwimmer; in cases where I am forced to use the hypodermic method I continue until manifestations have disappeared,—i.e., four to five injections,—Havas; usually until entire disappearance of symptoms,—Zarewicz; two months of .2 a week, or .1 a week, if patients are feeble,—Lassar; until disappearance of momentary syphilitic lesions,—Schweninger; about thirty days,—Caspary; as long as luetic symptoms are apparent and no mercurialism takes place; anyhow, twelve to eighteen injections of salicylate, each .08 to .1, in pauses from three to four days,—Doutrelepont; from six to eight weeks, one injection per week of 1 to 10 salicylate in paraffin oil,—Kopp; according to the cases, from one month to many months, from four to six, twelve, sixteen, or eighteen of .1 calomel,—Smirnoff; about one month,—Stoukovenkoff; according to case and always until disappearance of symptoms,—Polotebnoff; until disappearance of symptoms from four to six weeks,—Brouen; four to six weeks,—Noman; of calomel two or three injections at intervals of ten, of the soluble generally twenty to thirty days,—Pellizzari; of calomel three to six injections of .05 to .1, of sublimate .01 to .05 for one to two months,—Breda; no answer,—Gamberini; until all symptoms have disappeared,—Scarenzio; ordinarily, I make twenty-five to thirty injections, one every day,—Ferrari; variable,—Barduzzi; no answer,—Leloir; three to four injections of calomel,—Poncet; about four weeks for one attack,—Von Ins; until all symptoms are gone, and then use some treatment by the mouth,—McCall Anderson; during the primary and secondary stages,—Cruyl; in series of six to eight injections, repeated at intervals of two or three months or longer,—Wilson.

It is rather difficult to summarize the answers to question No. 6, although there seems to be a general tendency to continue the treatment up to the disappearance of all the symptoms, an opinion expressed by eleven of my correspondents; five continue the treatment

with sublimate injections for twenty or thirty days, one six to eight weeks, one two months, one three months; of calomel injections, from two to three, four to five, six to eight are given by six correspondents; eight, ten, and twelve of gray oil by another; ten to twelve of sozoiodolate, and twelve to eighteen of salicylate; while still another gives of the formamidate, in one and a half to two months, twenty-five to thirty-five injections; the benzoate is continued for one month by one, while three answer the question indefinitely, and three more not at all.

The answers to question No. 7, "What are the disadvantages and the untoward effects, if any, of the hypodermic treatment in your experience?" are somewhat variable and will be found difficult to classify.

The answers are as follows:

Reference to his publications,—Kaposi; in some cases dysentery,—Neumann; if only one dose, as stated, is injected at a time and the period of administration is observed, there will be no surprises from disagreeable accidents,—Lang; nothing,—Riehl; in the intramuscular injections of salicylates made superficial not very painful infiltrations; I never saw abscesses only with calomel, which I do not use; therefore, hypodermic injections have for practical reasons a disadvantage that they have to be made daily,—Finger; with antiseptic precautions we have only the ordinary appearance of mercurialism,—Mracek; when well applied, no disadvantages; had within ten years scarcely any untoward effect,—Hebra; abscesses, induration, pains,—Kohn; I have met, as with inunctions, salivation and gingivitis; with good injections and antiseptic precaution, I have seen with no preparation, soluble or insoluble, any abscesses,—Zeissl; I have never met with a fatal accident,—Pick; I could not see disadvantages, only infiltrations after calomel, and the best effects in regard to treatment,—Janovsky; I am always satisfied with this method, and have never seen disadvantages when injections were made with a clean needle and the general postulates of cleanliness,—Schimmer; in spite of careful dosage, assimilation of mercury is individual and not controllable; I have seen very marked mercurialism in some cases, such as anæmia, headache, anorexia, tremor, diarrhoea, and marked depression,—Havas; after hypodermic use of calomel I have seen one fatal case; after gray oil follow infiltrations and abscesses; gray oil is, moreover, very slowly absorbed,—Zarewicz; none at all,—Lassar; none,—Schweninger; no disadvantage from sublimate injections where they are well

borne; the advantage is accurate dosage,—Caspary; infiltration at the place of injection, stomatitis, and other mercurial symptoms, as they happen with every method,—Doutrelepont; cleanliness, prompt involution of symptoms, accurate dosage; applicable, especially in polyclinic and private practice, where inunction cannot be very well used,—Kopp; only in isolated cases marked pain, very seldom an abscess; the curative effect rarely ever fails,—Smirnoff; with correct employment one cannot have disagreeable complications,—Stoukovenkoff; advantages, rapidity and permanence of action, cleanliness of the method; disadvantages, at times local pain,—Polotebnoff; pains and indurations, sometimes at the place of puncture,—Brpuen; sometimes pain for twelve to fourteen hours; in some very rare cases an abscess,—Noman; pain in the use of sublimate and the other soluble salts; small abscesses occasionally when using calomel,—Pellizzari; with calomel in about four hundred cases, two abscesses, two enterocolites, four stomatitis, one sciatica; with sublimate one abscess, one stomatitis; with yellow oxide, in about one hundred cases, two enteralgias, with diarrhoea; with salicylate in eighty-five injections, one fever, five infiltrations, one gastroenteralgia,—Breda; indefinite answer,—Gamberini; unless you exceed proper dose, no danger or disadvantage,—Scarenzio; I have not one disadvantage to report,—Ferrari; none,—Barduzzi; refers to his publications,—Leloir; the injections of calomel are often painful; the action of calomel causes a general depression,—Poncet; stomatitis, bloody stools, hæmatemesis, collapse, which fortunately does not end fatally,—Von Ins; indurations, but rarely abscesses if proper precautions are used,—McCall Anderson; refers to literature,—Cruyl; pain, occasionally severe, though transient, and now and then nodular infiltration of tissues; in a very few instances abscess formation,—Wilson.

An analysis of this last series of answers shows that four correspondents give no direct information on the subject, but refer to publications; seventeen state that there are no disadvantages from the use of the soluble mercurials; while four mention the following disadvantages from the injection of this kind: one, dysentery; two, abscesses; one, mercurialism. In regard to insoluble mercurials, six report no disadvantages, while four report abscesses from calomel and from gray oil; two of the correspondents seem to have been particularly unfortunate with their experiences; one reports with calomel two abscesses, two entero-

colites, four stomatites, one sciatica; with sublimite, one abscess, one stomatitis; with yellow oxide, in about one hundred cases, two enteralgias with diarrhoea; with salicylate, in eighty-five injections, one fever, five infiltrations, and one gastro-enteralgia; while the other reports stomatitis, bloody stools with hæmatemesis, collapse, which, fortunately, did not end fatally. Truly, their experience seems to be quite at variance with that of others. One correspondent alone refers to a fatality from the use of calomel.

In view of the fact that it has been stated that the hypodermic method is not one that is well established, and that it lacked perfection, question No. 8, "Do you consider the hypodermic method well established?" is intended to elicit answers of great importance.

The answers are as follows:

Yes,—Kaposi, Neumann, Riehl, Zeissl, Pick, Janovsky, Caspary, Doutrelepon, Stoukovenkoff, Noman, Pellizzari, Barduzzi; it is only beginning to be appreciated in America,—Wilson; yes, certainly,—McCall Anderson; indefinite,—Von Ins; indefinite,—Poncet; no answer,—Leloir; the wide adoption of this method vouches for its stability,—Scarenzio; indefinite,—Gamberini; yes, I consider the hypodermic method as perfectly established on the best basis,—Breda; I believe this method is well established,—Polotebnoff; yes, perfectly,—Smirnoff; yes, I made until to-day more than one thousand injections without seeing abscesses; sometimes they are somewhat painful, there are nodular indurations at the point of injection, but the discomfort soon disappears,—Kopp; no,—Schweninger; perfectly,—Lassar; as a method by which the mercury can be introduced into the organism, yes; as exclusive treatment of syphilis, no,—Zarewicz; for the above-cited reasons it undoubtedly needs reform,—Havas; perfectly,—Schwimmer; a great many more experiences must be made in this method,—Kohn; very well,—Hebra; well established as a therapeutic method,—Mraceck; I consider the injection method well established, and on account of its accurate dosage scientifically rational,—Finger; I am perfectly satisfied that the method will gain adherents,—Lang.

While, in answer to this question, four of my correspondents give an indefinite answer from which no deduction can be drawn, one fails to state anything, and three consider it as not well established, twenty-eight give an unqualified approval as to the firm establishment of this method.

It has been further stated that many of those

who had used the hypodermic method, among them some of the best men both here and abroad, after thorough trial have discontinued its employment in the treatment of syphilis. My question No. 9, "Should it, in your opinion, be continued or abandoned as a regular treatment for syphilis?" will probably show the opinion of syphilographers abroad on this point.

The answers are as follows:

Continued,—Kaposi, Neumann, Mraceck, Hebra, Pick, Janovsky, Caspary, Doutrelepon, Kopp, Brouen, Ferrari, Barduzzi; by all means continue,—Wilson; to be continued always according to indications,—Cruyl; continued in suitable cases,—McCall Anderson; there is nothing against the hypodermic injections of soluble mercurials, and I therefore only use those,—Von Ins; this method is to be continued for grave cases,—Poncet; to continue, but to be employed with method,—Leloir; without doubt,—Scarenzio; I taught it as the most commendable,—Breda; I consider the hypodermic method is to be continued, but not as a general and exclusive treatment for all cases of syphilis,—Pellizzari; it should be continued as a regular treatment for syphilis without very alarming complications; in cases of iritis or brain syphilis, etc., we prefer the inunction treatment,—Noman; I will never give up this method,—Polotebnoff; syphilis requires a systematic treatment during two to three years, with intervals always more prolonged after each treatment,—Stoukovenkoff; calomel injections will, aside from inunctions, be the most powerful and most reliable method for mercurial treatment; calomel injections act even stronger than inunctions,—Smirnoff; I am not ready to answer,—Schweninger; it is indispensable and will be always continued,—Lassar; there are cases where the hypodermic method cannot be replaced by any other; for this reason it must be retained in the treatment of syphilis, otherwise syphilis may on an average just as well be treated by other methods,—Zarewicz; in some cases the hypodermic method is extraordinarily advantageous for patients and physicians, but as regular treatment I prefer inunctions,—Havas; I do not say that the other methods are not used, but I think that we could not be any more without it,—Schwimmer; I believe that we ought not to give up any of the heretofore used methods, with the exception of fumigation,—Zeissl; in some cases this method will always be made use of,—Kohn; I do not use the injections exclusively; I differentiate the two already-mentioned methods of mercurial treatment:

A, energetic (1) inunctions and (2) intramuscular injections with insoluble salts, equal in action; B, mild (1) internal medication, (2) hypodermic medication with soluble salts; these also equal each other in effect. With us in Austria the inunction treatment is still very much practised. I use it also when energetic action of mercury is indicated, and I make intramuscular injections when inunctions cannot be made either by inclination to mercurial eczema or for social reasons. No antisyphilitic treatment can be so easily kept secret as the injections. When I consider a mild mercurial effect indicated, then I use the protiodide, the tannate, or the sublimate internally; where gastritis and enteritis contraindicate the internal treatment, I use hypodermic injections of sublimate,—Finger; yes, for relapses in cases not grave,—Riehl; with limitations, which I pointed out, the continuation of the method is to be recommended,—Lang.

From the above answers it can be readily seen that the large majority of my correspondents are unqualifiedly in favor of continuing the method; while some place restriction on its use, or qualify indications for it, they, nevertheless, see and recommend a large sphere for its employment; while two of the correspondents do not answer the question and four give only an indefinite answer, thirty of the thirty-six favor the continuance of the method.

This brings us to the tenth and last question, "Do you consider it has superseded to a great extent the administration of mercury by the mouth in the treatment of syphilis?"

The answers to this question are important, especially to verify or otherwise stamp as unwarranted the statement that I have made in my previous paper, "That in the principal medical centres of Continental Europe little or no mercury is given internally any more."

The answers to this question are: Yes,—Kaposi, Neumann, Mraceck, Zeissl, Pick, Lassar, Schweninger, Doutrelepont, Barduzzi; it has with those who have given it a systematic trial,—Wilson; no,—Cruyl, McCall Anderson; no, I do not believe it, as the facility of the internal use of mercury in contradistinction to the inunctions and injections will always bring physicians and patients back to the internal use, which, with proper precautions, has scarcely any disadvantageous consequences,—Von Ins; I do not think that the hypodermic method is intended to disparage that of stomachal ingestion,—Poncet; no answer,—Leloir; I hold that the method of administration by the mouth is inferior to the hypodermic injections,—Ferrari; I cannot see any contraindications to the hypodermic methods other than to any other method of mercurial medication,—Scarenzio; the regular administration of mercury by the mouth, used for such a long time, merits in general the preference when the patients follow the rules laid down for it,—Gamberini; I prefer the method in grave cases and when I think it would not be done justly and regularly by other methods,—Breda; I believe not,—Pellizzari; it has superseded the administration of mercury by the mouth; we only employ the latter treatment in milder relapses of syphilis,—Noman; I think this method preferable to all others,—Brouen; the ingestion by the mouth I consider as perfectly superfluous,—Polotebnoff; the hypodermic method, by its promptitude and exactitude, surpasses by far the method by the mouth; the symptoms, for instance, which disappear in a month during oral ingestion, disappear in a week by the hypodermic treatment,—Stoukovenkoff; yes, because the internal treatment, either immediately or after some time, mostly deranges the stomach and thereby disables it from taking up further quantities of the remedy,—Smirnoff; administration of mercury by the mouth I think the most unreasonable and inexact thing in the world; nobody ever knows how much will be absorbed; finally, it very often produces irritation of the stomach and intestinal tract,—Kopp; I have ordered the internal use only seldom,—Caspar; the hypodermic method, in regard to its intensity, may be said to stand between internal administration and inunctions; a special preference over the oral ingestion it has not,—Zarewicz; I am a decided opponent of the indiscriminate mercurialization, not alone because it is superfluous, but because it is also disadvantageous to the organism, producing neurasthenia, and because it only acts on manifest syphilis symptoms,—Havas; I regard the value of this method in every case more efficacious than the internal administration of mercury,—Schwimmer; yes, because the administration of mercury by the mouth is insufficient,—Janovsky; the internal use of mercury will be permissible only, then, when we cannot reach our objective by injections,—Kohn; it has,—Hebra; I do not think that we ought to monopolize one method of treatment; our object in the therapy of syphilis is to get mercury in sufficient quantity into the organism; it depends entirely on the special case which way to choose to reach this end in the safest manner,—Finger; the treatment with mercury by the mouth is also good sometimes,—Riehl; certainly,—Lang.

In answer to this question, I have elicited twenty-three unqualified statements that the hypodermic method, in the opinion of my correspondents, had superseded the administration even of mercury by the mouth; some of them deriding the latter method and claiming positive disadvantages for it. Five of my correspondents give an indefinite answer from which no conclusion can be arrived at on this point, while seven out of the thirty-six do not consider that the hypodermic method has superseded that of oral ingestion; in many cases admitting, however, the value of the hypodermic method.

The general remarks made by twenty-two of my correspondents are more on the general treatment of syphilis, and so little to the objective point of this paper that I do not feel justified in prolonging its already vast scope by their introduction. In them many state their preference for inunction, which seems, especially with the Germans and Austrians, a general method of election. The courteous and lengthy communications of some of my honored correspondents well merit their reproduction as a consensus of opinion on syphilis and its treatment generally. It has been, however, my aim to present only such opinions as were directly on the injection treatment; and I must therefore reluctantly decline to introduce subject-matter foreign to my purpose.

When we analyze my communications geographically, it will be found that we have fourteen from Austria, six from Germany, four from Russia, one from Holland, seven from Italy, two from France, two from Switzerland, five from England, two from Belgium, and one from this country.

It seems to me that opinions on the subject of this method of treatment are divided somewhat by geographical lines. Thus, it will be found that among the five English correspondents only one endorses the treatment. This we can attribute no doubt to the teaching of Hutchinson and its influence. From France my two correspondents seem not greatly impressed with the utility and scope of this method; as much may be said of the two correspondents from Belgium and the same number from Switzerland. The methods of Sca-renzio are still adhered to by the Italian school, while the practice of Russia and Holland seems to lean towards the German and Austrian teachings. Five out of the six German correspondents appear as adherents of the hypodermic method, while of the fourteen Austrian correspondents, probably all but two may be said to be warm supporters of the injection treatment.

I could quote a number of Americans who have employed this treatment for some time, and have both in literature and privately expressed their favorable impressions of its value. I found it expedient to introduce but one of its supporters, because he was, perhaps, the earliest author in this country on the subject of calomel injections, and because by his position as a teacher and practitioner he can be said to carry more weight than others who followed in his footsteps, and whom I have, therefore, not felt called upon to cite here. It must be remembered that I have thrown out the testimony of all who have not been able to state their experience with this method. It should also be remembered that of thirty-two correspondents of Dr. White, in his admirable paper on this subject read before this Society, only seventeen have had experience with the method, of which fourteen were opposed to it and three spoke in its favor, while fifteen expressed themselves as having had little or no experience with it. Condemnation without trial or judging *a priori* without experience can hardly be assumed as a fair means to arrive at medical opinions. There is no doubt that the hypodermic method is not all or everything that is needed in the treatment of syphilis, but I think that it is one of the methods of treatment for syphilis which has a wide application and a vast field of usefulness.

The principal objection raised against it, that it cannot be used continuously for a number of years, it shares in common with probably the most efficacious method of medication known in the therapy of syphilis,—*i.e.*, the mercurial inunctions. That after its use there may appear again and again relapses is as true as that they may do so after inunctions. In these it is necessary to repeat the series of injections as well as it becomes necessary to repeat the treatment by inunction from time to time with the reappearance of the lesions which make manifest the recrudescence of the disease. With every series the lesions appear less severe and the necessity for mercurialization less marked. If, with the non-appearance of the symptoms within a period of years, the necessity for mercurial treatment ceases, the assumption for a cure of syphilis by this method is as much justified as by a continuous oral ingestion of mercurials during that time. That there are quite a number of cases in which there is no reappearance of syphilitic lesions after the first or possibly the second series of injections, especially if the series has extended over a sufficiently long period of time, and that the necessity for further medication then ceases, is a fact

quite as obvious as that reported and observed by many, that syphilis will disappear often even without treatment, or under the influence of proper hygienic, dietetic, and sanitary conditions only.

If I am justified in drawing any conclusions from the answers to my questions, I would sum up as follows:

1. The hypodermic use of mercurials is largely employed in the treatment of syphilis in Continental Europe, with probably the exception of France.

2. While all of the many preparations of mercury find employment in this treatment, the one by preference is sublimate, next in order calomel, then salicylate, followed by yellow oxide, also sozoiodolate and gray oil; the others seem to be favored by individual adherents only.

3. That there appears to be a decided preference for the soluble over the insoluble preparations.

4. As to rapidity of action and permanence in effect, calomel seems to hold the foremost place.

5. There seems to be no doubt, judging from my investigation, that in that part of the European continent mentioned the hypodermic method (I include here also the intramuscular injections) is being freely employed as a general treatment for syphilis.

6. The period of time through which the hypodermic treatment is being continued in the average cases cannot be said to be strictly limited, but should be until all symptoms have completely disappeared.

7. The opinions of my correspondents on the disadvantages and untoward effects of this treatment would show that they are not nearly as frequent or as serious as has been supposed, and that they are by far more frequent with the insoluble than the soluble preparations. It seems to be the general opinion of a majority of my correspondents that serious complications may be avoided with proper care and cleanliness. The testimony of a few individual ones seems in this respect greatly at variance with the experience of a large majority. Accidents such as may arise in the course of all methods of mercurialization cannot, of course, be specially attributed to the hypodermic treatment.

8. The question as to the firm basis on which the hypodermic method is established is answered almost universally in the affirmative.

9. The consensus of opinions of my correspondents as to whether the hypodermic method should be continued or abandoned as a regular treatment for syphilis tends towards the almost

universally expressed desirability of its continuation, although in the minds of a small minority with certain limitations or restrictions.

10. There seems no doubt, from the nature of the responses I have received and quoted above, that I was justified in claiming some time ago "that in the principal medical centres of Continental Europe little or almost no mercury is given internally any more in the treatment of syphilis," and that in the countries mentioned hypodermic medication has superseded oral ingestion of mercurials to a great extent.

*A CLINICAL INVESTIGATION TO DETERMINE THE VALUE OF CORROSIVE SUBLIMATE AND THE GRAY OIL ADMINISTERED HYPODERMICALLY IN THE TREATMENT OF SYPHILIS.*

BY ORVILLE HORWITZ, B.S., M.D.,  
Clinical Professor of Genito-Urinary Diseases in the  
Jefferson Medical College; Surgeon to the  
Philadelphia Hospital, etc.

THE experience of many investigators is adverse to the employment of the insoluble salts of mercury hypodermically.

The general belief is that the use of these salts results in great pain and produces callosities, abscesses, and stomatitis. Our experience corresponding with those of other observers, we some time since determined to enter upon a clinical investigation to ascertain, if possible, the value of both corrosive sublimate and the gray oil in the hypodermic treatment of syphilis.

These remedies, it is believed, we have fairly and fully tried. The result is here recounted, that all may judge of the value of our observations.

The first experiments were made with a view to ascertain whether the disease could be aborted after the method suggested by Bronson, who has recently advised hypodermic injections of mercurials into the chancre and the indurated lymphatic glands in its neighborhood. His views are based upon the theory that the initial lesion is the storehouse of the syphilitic poison, or the point during the primary stage from whence the disease is disseminated; and that the mercurial being brought into direct contact with the micro-organism which causes syphilis, necessarily exerts its germicidal influence, destroys it, and thus aborts the disease.

Ten cases were selected and placed under treatment. A quarter of a grain of corrosive

sublimate was administered daily to each hypodermically until thirty injections had been made. It was possible to insert but three or four injections at the site of the chancre; the remainder were introduced into the indurated glands about the groin. These injections were attended with slight pain and more or less oedema of the penis.

A suppurating bubo made its appearance in but one instance. Whether or not this was caused by the treatment could not be determined, as a certain proportion of syphilitic cases will always be accompanied by a complication of the kind.

In nine of the cases the symptoms were delayed, and did not appear for a period varying from between two and nine months after all treatment had been discontinued. The manifestations were very mild, taking on the form principally of mucous patches, slight alopecia, and macular eruptions. In the tenth case, although over one year has elapsed since the disease was contracted, no untoward symptoms have appeared.

With this patient the doubt as to a correct diagnosis must be taken into account, for the origin of the disorder might not have been syphilitic.

As far as can be determined, this method of treatment simply delays the appearance and mitigates the symptoms of the disease, rendering it difficult to give a correct prognosis, and leaving it uncertain in the mind of the practitioner how long treatment should be continued.

Sixty cases of secondary syphilis were selected for the purpose of investigation and to determine as far as practicable the value of this method of routine treatment. The quantity of corrosive sublimate employed was a quarter of a grain to each injection. Each patient received thirty injections, making, in all, eighteen hundred hypodermic insertions.

Fifteen patients were inmates of the Philadelphia Hospital, thirty of the Jefferson Medical College Hospital, and fifteen were selected from private practice.

The cases that were treated at the Philadelphia Hospital quitted the establishment within a month and could not be followed; of those treated at the Jefferson Hospital, nine have not been heard from since being discharged; of the remaining twenty-one still under observation, eleven have relapsed, and have been placed on other forms of treatment. Of the fifteen private cases, four have not been heard from since they have been discharged; and of the eleven remaining cases, three have relapsed, and eight up to the present time remain in good health.

The longest period that has elapsed since the treatment of the last case is six months. Most of these relapses occurred within from four to eight weeks after the injections were discontinued. None of the patients made any special complaint of pain produced by the injection; in no instance was an abscess formed, nor was there induration about the seat of the injection. When relapses took place, several of the patients were desirous of returning to the use of the hypodermics. In all the rapid disappearance of the symptoms was remarkable. In most cases, as a rule, constipation prevailed, and the employment of salines became necessary. In no instance was salivation produced.

So that in sixty patients on whom the hypodermic method had been employed, on each of whom thirty injections were administered, twenty-eight disappeared and are unaccounted for; the remaining thirty-two have been carefully watched.

Of this number, fifteen relapsed within eight weeks after treatment had been discontinued, leaving seventeen free from disease. The longest period that has passed since any of these has received treatment is ten months.

The advocates of this method advise that, when recurrence takes place, injections be resumed, reducing the dose, however, to one-sixth of a grain of corrosive sublimate, returning to the mercurial whenever the disease reappears, and reducing the amount of the drug on each occasion.

This rule was not followed in the relapsing cases here referred to after thirty injections had been used without good results. It appeared to us merely a symptomatic method of treating the disease, which is generally fraught with so much danger, tertiary lesions usually following.

The supporters of the routine method of treatment by hypodermic injections of corrosive sublimate agree that about forty per cent. of the cases relapse. It will be observed that with us well-nigh fifty per cent. recurred, and that the disease returned in a remarkably short time after treatment had been discontinued, the longest period of exemption being eight weeks.

In order to determine the value of the hypodermic injections, when used in conjunction with other methods, nineteen cases were submitted to treatment. In five of these the lesions were situated upon the face, and were a source of great annoyance; hypodermics of corrosive sublimate were administered, when the eruptions disappeared with remarkable rapidity. Mercury was then administered by the mouth.

In fourteen cases of severe syphilitic poison a systematic course of treatment was pursued. For a period of four months the mercurial was administered by the mouth, and instead of making use of inunctions of mercury for two weeks, which is the usual method, injections of a sixth of a grain of bichloride were given daily for that length of time, when these were discontinued and the administration of the drug by the mouth resumed.

In the case of a married man who contracted syphilis in the absence of his wife during the summer, and who expected her return within three weeks, and who was most anxious that no symptom of the disease should be present on her return home, eighteen hypodermics were administered, with the result that at the end of twenty-one days he was perfectly free from all manifestations.

In two cases of iritis fifteen injections of corrosive sublimate were administered in each case, the patients taking in conjunction ten grains of the iodide of potassium three times daily, when the symptoms rapidly disappeared.

In a rare case of gumma of the conjunctiva, occurring in the clinical service of Professor Thompson, eight hypodermics caused its disappearance, when treatment was continued by the mouth.

In four cases of relapsing syphilis hypodermics of gray oil were given once a week for six weeks, and although nearly a year has elapsed since treatment has been discontinued, these patients, who were constantly suffering from manifestations of the disease, have remained free from any symptoms. With these cases all other methods heretofore employed had failed.

In one case of gumma of the palate the pain produced by the corrosive sublimate was so severe that the injections had to be discontinued after two administrations, when other means were resorted to.

In three women who were inmates of the venereal ward of the Philadelphia Hospital, and who had been on a continuous course of treatment by the mouth before the hypodermic method was employed, slight ulceration of the gums was produced, and the injections were necessarily discontinued.

In one case of gumma of the brain fifteen hypodermics of the gray oil, in conjunction with small doses of iodide of potassium, effected a rapid cure.

In one case of syphilitic insanity six hypodermics of gray oil were given with marked improvement.

In two cases of syphilitic locomotor ataxy the staggering gait, the great pain, and the vertigo

have almost entirely disappeared, and there has been a progressive increase of weight and strength; both patients, who were unable to work when first placed under treatment, have returned to their respective occupations. The gray oil was likewise employed in twelve cases of obstinate skin-eruptions which refused to yield to other methods of treatment.

In eighteen cases of secondary syphilis, which had shown constant tendency to relapse during a course of two years' treatment, and in one case of malignant syphilis, marked improvement was manifested by the treatment here recommended.

The following table exhibits the number and conditions of the cases and the number of hypodermics of corrosive sublimate administered in each instance:

No. of Cases.	Conditions.	No. of Hypodermics.
10	Attempt to abort the disease .....	300
60	Routine treatment .....	1800
6	Obstinate skin-eruptions .....	180
5	Eruptions on the face .....	110
14	Conjunction with systematic treatment .....	196
1	Married man .....	18
2	Iritis .....	30
1	Gumma of conjunctiva .....	8
99		2642

A second table is submitted, exhibiting the conditions of the patients and the number of hypodermics of gray oil administered in a given number of cases:

No. of Cases.	Conditions.	No. of Hypodermics.
2	Gumma of the brain .....	12
1	Insanity .....	6
2	Locomotor ataxy .....	12
4	Relapsing syphilis .....	24
12	Obstinate skin-eruptions .....	72
18	Termination two years' course treatment ....	108
1	Malignant syphilis .....	6
40		240

From a careful study of the clinical cases just cited the following deductions may be drawn:

1. Hypodermic medication will not abort the disease.
2. That it should not be employed as a routine method of treatment.

3. That the production of abscesses or of pyalism by this method must be very rare.

4. Injections of corrosive sublimate give rise to trifling pain, but not to callosities.

5. The gray oil gives rise to slight pain and always produces induration.

6. The gray oil employed in this manner is more dangerous than corrosive sublimate, and when administered the patient should be carefully watched.

7. In suitable cases, when properly employed, these remedies are among the strongest weapons possessed by the profession wherewith to fight the disease.

8. When employing corrosive sublimate, a quarter of a grain should be administered with each injection, provided the patient has not previously been submitted to treatment; if mercurials have already been employed by the mouth, the quantity employed should be one-sixth of a grain.

9. Hypodermic injections of corrosive sublimate are of undoubted value when the lesions appear upon the face and a rapid impression is desired; likewise when some important structure, as the eye or brain, is attacked.

Mercurials may be employed hypodermically as a substitute for inunctions in a systematic course of treatment.

They may be used with advantage when time is an object.

In cases of relapsing syphilis where other methods have failed, injections have completely controlled the outbreak.

In syphilitic diseases of the nervous system their use generally produces most satisfactory results.

They are frequently beneficial in those forms of eruption that have proved rebellious to other treatment.

10. It is well to employ the gray oil in cases of severe secondary syphilis where there is evidence of a tendency to relapse during the course of a two years' treatment, winding up with a weekly administration of a hypodermic for the space of six weeks. The patient should then be placed upon small doses of iodide of potassium for the period of three months. This treatment is valuable in the obstinate relapsing tertiary variety of the disease, and has proved more potent in our hands than any other method. In nervous syphilis it is far superior to inunctions.

*Finally.*—This mode of treatment is unhesitatingly recommended to the profession, under the conditions already laid down, as the most reliable and active that can be employed.

#### ASEPSIS IN OBSTETRICS.

In a short paper in the *Brooklyn Medical Journal* of April, 1894, GORDON gives the following directions as those employed by himself in obstetrical practice. He instructs the patient to have ready two wash-bowls and a hand-brush for each, a dozen pieces of boiled cheese-cloth for wash-cloths, and the following prescription for lubricating the hand:

R Hydrarg. bichl., gr. i;  
Glycerin, ℥ii. M.

Also a bottle of bichloride-of-mercury tablets.

When labor begins have the bowels emptied by an enema and the external genitals thoroughly cleansed with soap and water. Before a digital examination the parts are bathed by the nurse with a bichloride-of-mercury solution (1 to 2000), and the hands and arms of the examiner thoroughly scrubbed with soap and hot water, rinsed, and again washed in a 1 to 2000 bichloride-of-mercury solution, the fingers lubricated with the antiseptic glycerin solution, the hand to be immersed in the bichloride solution before each succeeding examination, which are as few as possible. At the close of the third stage the external genitals are cleansed by the nurse (whose hands have been rendered aseptic) with an antiseptic solution, and a napkin applied, which has been wrung out of a bichloride-of-mercury solution and dried.

Should catheterization become necessary, the same antiseptic precautions are observed. No douches are used after normal labor. In instrumental cases the instruments are first immersed in boiling water and then in a five-per-cent. carbolic-acid solution. After delivery, a hot carbolized douche is administered.

#### STERILIZATION OF HYPODERMIC SOLUTIONS.

D. MARINUCCI has found large numbers of living germs, some of a harmful nature, in freshly-prepared hypodermic solutions of strychnine sulphate, morphine hydrochlorate, atropine sulphate, eserine, etc. Sterilization by heat did not affect the therapeutic value of strychnine and quinine, but partly checked the action of morphine and atropine. Eserine and atropine solutions are said to be best prepared with a solution of corrosive sublimate (1 in 1000), which renders them aseptic without modifying their therapeutic properties. It is suggested that all such solutions should be renewed every fourteen days.—*Druggist's Circular and Chemical Gazette*, March, 1894.

### THE TREATMENT OF ENLARGED CERVICAL GLANDS.

LEAVING out of consideration malignant disease and general lymphadenoid enlargement associated with profound blood-changes, enlarged cervical glands as they appear to the clinician can generally be classed as irritative or tubercular. These enlarged glands are commonly found in the neck, the axilla, or the groin, by far the large majority being placed in the cervical region.

They are more frequent in children than in adults. The simple irritative form is characterized by a somewhat rapid course, terminating speedily in either resolution or suppuration. The tubercular form is slow in course, progressive, prone to involve an entire chain or, indeed, all the glands of the neck, and usually terminates in caseous degeneration of the deeper

glands and in softening and ulceration of the skin overlying those more superficially placed. After the process has developed thus far, the tubercular matter may become encapsulated, or may be spontaneously extruded; the patient may definitely recover. Frequently, however, the disease passes down to the mediastinal glands, becomes wide spread, and death ensues. The entrance-point of infection is usually the mucous membrane of the nose, the mouth, or the pharynx.

The frequency of cervical tubercular adenitis makes the question of therapeutics one of great importance. In the discussion on this subject in the Section on Diseases of Children, at the annual meeting of the British Medical Association, Teale took the ground "that (*British Medical Journal*, No. 1717, 1893) whenever septic material is contained in the system, we rest not until it is expelled and its burrows are laid open and disinfected. In doing this the surgeon must make it an artistic study how to effect his purpose with the smallest possible amount of blemish. The ugly scars and unseemly depressions, once so familiar in scrofulous necks, should be deemed an opprobrium of surgery; while to delay operation until the skin is thin, red, and ready to break down, or has already given way, should be looked upon as mischievous trifling."

He expresses the hope that the time is not far distant when the absolute inutility of painting the skin, in the hope of influencing a caseating gland deeply seated beneath muscle and fascia, will be fully realized by the professional mind, and lays down the following propositions for the guidance of the surgeon in the operative treatment of these cases.

1. Whenever fluid—that is, pus—can be detected in connection with a diseased lymphatic gland, the operation should be done before the skin becomes red and thin.

2. When the diseased gland is subcutaneous,—that is, not beneath the deep fascia or muscle, and has been completely removed,—the least scar will result if neither stitches nor drainage-tube be used, especially if it be possible to leave the wound uncovered by dressing and exposed to the air, so that the edges may be drawn and glued together by drying lymph.

3. If the diseased gland is beneath the muscle or muscular fascia, then a drainage-tube must be used, and the edges of the wound must be united by suture. The best drainage-tube is the gilt spiral wire, especially as it may have to remain from two to eight or ten weeks, according to the depth of the wound or the completeness of the removal of the gland.

4. Where many glands have to be removed, it is better to remove them through a series of small incisions and thereby avoid very extensive ones.

Considering the subject from a pathological point of view, he holds that all sinuses and suppurating cavities should be thoroughly cleansed by means of scraper and lint, so as to leave a fresh surface free from granulation or decayed or decaying tissue, and that a drainage exit should be maintained until all the deep parts are healed.

It is essential to know and to bear in mind that the visible abscess, which has often been called and treated as a suppurating gland, is frequently but a subcutaneous reservoir of pus, the source of which (a degenerate gland) is not subcutaneous but superficial,—that is, under the deep cervical fascia, and often submuscular, under the sterno-mastoid, the communication between the two being a small opening in the deep fascia just large enough to admit a probe or director. This opening may easily be overlooked, and is not always easily found even when searched for, but it must be found, or the operation will be a failure.

No such abscess should be opened without putting the patient under ether and being prepared for all necessary means of eradicating the diseased gland. If, during the extirpation or evisceration of the gland, the finger detects in the wall of the capsular cavity the slight convex bulging of a contiguous gland, this should be pricked through the wall of the cavity, and so reached and extirpated or eviscerated.

As to caseous glands when a broken-down gland is encountered which is proved to have undergone caseous degeneration, it is safe to infer that any other enlarged glands then present or subsequently appearing are becoming caseous also. Therefore such glands should be removed as soon as the surgeon is convinced that such enlargement is persistent and not transitory, without waiting for evidence of fluctuation or pus.

As to simple glandular enlargement, Teale expresses no opinion in regard to operation. The instruments which have proved of most service to him are the special director devised by himself; Bigelow's dilator, for widening deep sinuses and avoiding the use of the knife in dangerous regions; Lister's scraper, which is a better form of instrument than Volkmann's spoon; a scalpel of proper lancet shape.

In regard to the ultimate effect upon the health, Teale holds that it is possible in most cases to get to the bottom of the trouble in one or two operations; that in most instances dis-

ease of the cervical glands, whatever its origin, is practically a local disease and needs to be dealt with by local measures, and that it is but rarely the expression of a general constitutional defect.

W. K. Treves states that he has operated on several hundred cases without a single death. He states that in operating the chief points are to avoid wounding or tearing the affected glands,—to keep, in dissecting, close to the surface of the gland, in order to avoid hemorrhage, and to use transverse incisions. Drainage-tubes are discarded, the wounds being closed and covered in by a pressure bandage.

Godlee, as a routine practice, advises cutting out of the glands in all cases excepting where there is reason to believe that the mischief has extended beyond the limits which can be marked by the knife, and those in which the glands have suppurated and become diffused. In the latter class of cases Volkmann's spoon is employed. He advocates small incisions, and never found it necessary to divide the sterno-mastoid. He prefers a free incision and complete removal. Drainage-tubes are used. He employs a blunt periosteum elevator in digging out glands from inaccessible parts. He has never seen general tuberculosis follow the scraping out of glands, though he has several times seen it follow the use of the instrument in other tuberculous conditions. He never uses a drainage-tube when he can get a clean-cut wound. He has lost no case from operation.

Marsh stated that the cases best suited for the proceeding were those in which glands were of the same size and of long duration, and had not yet suppurated. He advocated a free incision and complete removal. Drainage-tubes were used only when suppuration had occurred and where there was a deep and ramified cavity. Careful dissection is to be preferred to scraping.

Cummins referred to two cases in which extensive operations in the neck and axilla had been followed by acute phthisis. This unfortunate result he believed to be due to opening up of collections of tuberculous material and large blood-vessels during the operation. He believes in early excision of the gland, if possible, even if suppuration and adhesion of the gland to the surrounding tissue has taken place, in preference to the possibly incomplete removal of half-softened tissue by means of the scoop.

Medicinal treatment—*i.e.*, syrup of the iodide of iron—he considers harmful, but has seen benefit follow the prolonged use of the sulphide of calcium.

Thomas advocates the chlorate of potassium in 3- to 10-grain doses, and still more highly arsenic. He records one case in which he divided the sterno-mastoid and then drew up some glands from the thorax. The wound healed favorably, but the patient died fifteen months after from extension of the disease to the bronchial glands.

Milburn cautioned against too early recourse to operation. Removal in some instances, he said, had a good effect; in others it seemed to develop latent diseased conditions. Thus, in one case of constant and intractable corneal ulceration and opacities which had resisted all modes of treatment, removal of a suddenly-enlarged cervical gland was followed by clearing up of all the opacities and restoration of the child to apparently perfect health.

Noble Smith advocated a free opening and closure of the wound without using a drainage-tube. He held that section of the sterno-mastoid is followed by no ill effect.

Black called attention to the necessity of paying proper attention to the mucous membrane of the throat and nose in these cases.

It is worthy of note that in all this discussion no mention has been made of parenchymatous injections and treatment which have in recent years been widely advocated by those most experienced in dealing with the local forms of tuberculosis. Though it is undoubtedly true that early operation and complete removal by the knife offer the best chance of radical cure and with the least resulting deformity, it is, unfortunately, the case that many of these patients never present themselves until the disease has extended so far that complete removal by surgical operation is impracticable. In such cases the parenchymatous injections hold out a fair prospect of cure. Of these, the favorite seems to be a ten-per-cent. iodoform emulsion in glycerin. By means of a hypodermic syringe this mixture should be driven directly into the centre of infiltrated masses. The injection should be made at many points, and particular attention should be paid to forcing the medication into the periphery of the infiltrate. Twenty to 30 minims may be employed at each treatment, and the treatments may be repeated every third or fifth day. There is little danger of toxic symptoms. The ethereal solution of iodoform, at one time warmly advocated, is extremely irritating, causes great pain, and has produced death from iodoform-poisoning in a number of instances. French authors warmly commend solution of chloride of zinc. This is Professor Lannelongue's sclerogenic method; 3 to 4 drops of a 1 to 40 lotion are driven into various points of the en-

largement, the injection being repeated at each visit as often as the patient's tolerance of pain allows. This treatment is repeated every seven to ten days, and is finally terminated by injections 1 to 20 in strength.

Kanasz commends essence of cloves dissolved in olive oil in ten-per-cent. solution. When there is pus, this is first withdrawn. The treatment is repeated once in seven days. Indeed, when the subject of parenchymatous injections is considered, there are found so many drugs which are alleged to bring about useful results that it is hard to choose from them.

The internal treatment in these cases should consist in the use of cod-liver oil, iron, and a properly-regulated diet. Medicine administered for the purpose of acting directly upon the enlarged glands seems to be of little avail, though of the drugs used, syrup of the iodide of iron, in doses of 5 to 10 drops three times daily; iodide of potassium, in doses of 5 to 10 drops three times daily; sulphide of calcium,  $\frac{1}{2}$  grain, four times a day, are warmly commended. It is worthy of note that in operating upon deep glands which have already softened, drainage is unnecessary, since the ordinary micro-organisms of suppuration are entirely absent, and the inoculation of the pus by nutrient gelatin gives negative results.

#### *THE TREATMENT OF CERTAIN TYPES OF CONJUNCTIVAL HYPERÆMIA.*

IN a recent number of the THERAPEUTIC GAZETTE (October 16, 1893) we called attention to certain mild conjunctival inflammations and their local treatment, laying particular stress upon the importance of avoiding active astringents—as alum, sulphate of zinc, and particularly nitrate of silver—in the management of the types then described. When the conjunctival affection assumed a hyperæmic type, abnormal secretion being practically absent, and the congestion largely confined to the bulbar conjunctiva, the local measures recommended were the Koenigstein douche and washing the eyes frequently with tepid water and Castile soap. It was presupposed that the cause of the hyperæmia, so far as ascertainable, had been removed,—namely, local irritants, lachrymal obstruction, diseases of the naso-pharynx, various states of depraved health, vaso-motor disturbance, and eye-strain in the widest acceptance of the term.

It is the purpose of the present note to call attention to some types of hyperæmia more or

less characteristic of these states of depraved health and vaso-motor disturbance, many of which are associated with a corresponding hyperæmia, irritation, or positive inflammation of the naso-pharynx.

Perhaps the most interesting of these forms of conjunctival hyperæmia, several times referred to in the pages of the GAZETTE, is the one seen with gout, analogous in its manifestations to the "hot eye" described by Mr. Hutchinson,—a condition which will not subside under local treatment, and which presents somewhat the following train of symptoms: well-marked bulbar injection, the posterior conjunctival vessels being distinctly tortuous and filled with darker blood than is normal; practically no abnormal secretion, save perhaps a little frothy mucus at the inner and outer angles; no dread of light, but an annoying sense of heat, amounting sometimes to positive burning, present whether the eyes are used or not, but aggravated during close work. These symptoms are usually worse in the first hour or two of the morning, decrease during the day, but return soon after the evening meal, or in the presence of artificial light. There is nothing characteristic, and the hyperæmia resembles that which might occur from any of its well-known causes, the difference being that under anti-gout treatment, both medicinal and that which regulates the diet, more particularly the latter, the redness disappears. Sometimes the congestion remains, but its most troublesome symptom—the sense of heat—subsides. The practical deduction is the importance of ascertaining the probable relation of gout to any form of hyperæmia that persists in spite of the ordinary treatment. It should be remembered, even in these constitutional types, that all local measures which tend to relieve congestion are indicated, as well as the correction of refractive errors and the removal of naso-pharyngeal irritations.

Mr. Berry, in his excellent text-book, refers to a recurring form of hyperæmia of the conjunctiva, acute in character, which he suggests is due to some vaso-motor disturbance. This interesting type is seen in patients who exhibit abnormal flushings elsewhere in the body,—for example, spots of capillary injection in the face and burning and redness of the ears. Generally the cause resides in some condition dependent, as Mr. Berry says, on the lack of vaso-motor control, or the affection is associated with functional circulatory disturbances,—such, for example, as occur under the influence of the excessive use of tobacco. The

plain indication for the treatment is the removal of the cause and the exhibition of vaso-motor tonics, notably the sulphate of strychnine or very large doses of the tincture of nuxvomica. Ergot, with or without small doses of the bromides, occasionally acts well. Again, it must be remembered that these constitutional measures do not exclude local means; but when the two are combined, excellent results will usually follow.

Finally, we come to the form of hyperæmia of the conjunctiva, well known to all practitioners of medicine, both special and general, which depends upon torpidity of the liver, or, in general, to disturbances of the function of this organ. This is a characteristic bloodshot, watery eye, utterly rebellious to local treatment, and improving only when the hepatic functions are restored to normal. It is a waste of time to order for these patients collyria of various types, or even glasses, in the hope of relieving the congestion, if its prime cause is not recognized. Regulation of the habits of the patient, especially as to drink and food, calomel, podophyllin, and nitro-muriatic acid, each in its proper place, are often more indicated than antiseptic lotions, douches, and ordinary astringents.

Conjunctival hyperæmia is a troublesome complaint and worthy of thorough investigation, especially as it may be one of the symptoms of a general condition.

#### "CEREBRINE" AGAIN.

MANY of the readers of the THERAPEUTIC GAZETTE remember that we called attention in the GAZETTE of August 15, 1893, to the character of the preparation known as "cerebrine," introduced into medicine by Dr. William A. Hammond, of Washington. Shortly after there appeared in the *Journal of the American Medical Association* of August 26, 1893, a letter by Professor Brower, of Chicago, accompanied by another from the well-known chemist, Delafontaine, in which good physiological and chemical reasons were advanced for believing that the "cerebrine" obtainable in the market at that time had been sophisticated with no less powerful a remedy than nitroglycerin. About the same time the studies of Dr. Stockwell, of Detroit, also appeared, indicating that the first preparations of "cerebrine" which were placed upon the market by the Columbia Chemical Company, under Dr. Hammond's endorsement, were devoid of this substance, and it is therefore inferable that

sophistication was resorted to both to increase the activity of an otherwise inert substance and at the same time to produce this fortification by means of a substance which was not readily detected upon analysis. Since then a number of reports from other physicians have appeared, the consensus of opinion being that "cerebrine" in itself was unworthy of consideration by the medical profession as a remedy.

Finally, we have just received a letter on the subject written by Professor Albert B. Prescott, of the University of Michigan, at Ann Arbor, who is so well known to physicians and pharmacists through his work on the Committee of Revision of the United States Pharmacopœia, and to chemists because of his high rank in his chosen profession, which will be found under the head of "Correspondence."

It seems evident, therefore, that the position which we took in regard to the nature of this preparation last August was correct, and that the theoretical deductions naturally made at that time have been confirmed by the most competent of investigators. Fortunately, the facts were discovered ere the profession in general suffered from its too ready belief in the therapeutic recommendations of the originator of this now widely and popularly advertised product. This warning has forced the placing of the substance on the general market, it being widely advertised in the daily papers and recommended for popular use in association with Dr. Hammond's name, as may be seen from the following clipping from the New York *Sun* of March 27, 1894:

## THE ANIMAL EXTRACTS

Prepared according to the formula of

**DR. WM. A. HAMMOND,**

In his laboratory at Washington, D. C.

**CEREBRINE**, from the brain, for diseases of the brain and nervous system.

**MEDULLINE**, from the spinal cord, for diseases of the cord. (Locomotor-Ataxia, etc.)

**CARDINE**, from the heart, for diseases of the heart.

**TESTINE**, from the testes, for diseases of the testes. (Atrophy of the organs, sterility, etc.)

**OVARINE**, from the ovaries, for diseases of the ovaries.

**MUSCULINE**, thyroline, etc.

Dose, Five Drops. Price (3 drachms), \$2.50.

The physiological effects produced by a single dose of Cerebrine are acceleration of the pulse with feeling of fulness and distention in the head, exhilaration of spirits, increased urinary excretion, augmentation of the expulsive force of the bladder and peristaltic action of the intestines, increase in muscular strength and endurance, increased power of vision in elderly people, and increased appetite and digestive power.

Where local druggists are not supplied with the Hammond Animal Extracts they will be mailed, together with all existing literature on the subject, on receipt of price, by

**THE COLUMBIA CHEMICAL CO.,**  
Washington, D. C.

For sale by J. Milhau's Son, 183 Broadway; wholesale, John H. Francis, 83 John St.

## THE TREATMENT OF SYPHILIS BY HYPODERMIC INJECTIONS.\*

AS many of the readers of the THERAPEUTIC GAZETTE are aware, the subject of this editorial has been warmly discussed by syphilographers in this country and abroad during the past few years. Perhaps the most able summary of the treatment of this wide-spread disease by this means is that which can be found in a recent article on syphilis by Dr. R. W. Taylor, in the "System of Therapeutics;" but we notice that, although his paper was in many respects decisive, that wide differences of opinion still exist in regard to the value and indications governing the use of injections of mercury in specific disease.

During the past year a spirited discussion as to the advantages of these mercurial injections took place between Dr. Lawrence Wolff, who favored them, and Dr. J. William White, who opposed them, at a meeting of the Philadelphia County Medical Society. The conclusions arrived at by Dr. White were published in the THERAPEUTIC GAZETTE. Although at first glance White's views seem to be distinctly opposed to the use of the hypodermic injections, in reality we believe that to a great extent the ground taken therein is more moderate and correct.

It is the history of matters medical that all methods of treatment which are new are heralded with a blast of trumpets, which in many cases ends in a very feeble note of praise when sufficient experience has been accumulated by a number of observers to reach correct conclusions as to their value. We believe that the proper attitude for the general practitioner to assume in regard to the treatment of syphilis is about as follows: namely, that hypodermic injections of mercury are not to be resorted to if they can be avoided, or, to express it differently, unless strong indications for their use are present.

There are two recent instances in which methods of treatment have been strongly urged, and in which a sufficient time has elapsed to permit these methods to find their proper level. The antipyretic drugs, about

\* Since this leading article was written the two valuable papers on this topic, published in this issue of the GAZETTE, by Dr. Wolff and Dr. Horwitz, were received. The leading article is published as written as a short, third contribution to the subject, written independently of these papers. The paper found in our original columns is Dr. Wolff's second contribution to the subject, not the one referred to in the editorial.

which there was such a furore some years ago, are now only resorted to when other means for reducing fever cannot be utilized. They have been found to fall short of the great things that they promised when first introduced, and they have risen above the position accorded to them by practitioners with pessimistic views, who declared them absolutely useless. Similarly, we now know that hypodermic injections of quinine are never to be employed unless the condition of the stomach and rectum prevent the administration of the drug by the ordinary channels, or unless the malarial poison is acting so strongly as to demand the administration of quinine by every possible avenue of entrance into the body. We believe that the ultimate conclusion of the profession in regard to the hypodermic injection of mercurials in syphilis will certainly be identical with that governing their use of quinine in malarial fever. There can be no doubt that a certain number of instances do arise in which, by reason of severe infection, susceptibility of the patient, or inability to take mercury by the ordinary means, hypodermic injections are absolutely necessary. In the same way that we give quinine by the mouth, the rectum, and hypodermically in pernicious malarial fever, so do we give mercury by the mouth, by inunctions, by sublimation, and by the hypodermic needle in malignant syphilis. Our reasons for believing that hypodermic injections of mercurials are not to be resorted to as a routine treatment of syphilis are several. In the first place, all forms of hypodermic medication possess disadvantages not possessed by the use of drugs by the mouth. There is always some danger of entering a vein, of producing an abscess, or of causing local pain. When mercurials are so employed, the danger of abscess, of pain, or of milder inflammatory manifestations is greatly increased, and the presence of an indurated spot where the hypodermic injection has been given proves that it is not the simplest form of medication in syphilis.

Of the mercurial preparations which are best administered hypodermically in syphilis, the two which surpass all others are undoubtedly the bichloride of mercury, in the dose of  $\frac{1}{10}$  grain, dissolved in 10 or 15 drops of distilled water, every second or third day, or gray oil, or oleum cinerium, which was first introduced into medicine by Lang, of Vienna.

In all cases the injection should be given deeply and in some portion of the body in which the tissues are loose, as the buttock or the broad of the back. Gray oil, it will be remembered, is prepared as follows: two drachms

of lanolin is rubbed up with enough chloroform to emulsify it. The rubbing process is continued until most of the chloroform is evaporated, and while the mixture is still in a fluid state, metallic mercury in double the amount of lanolin—four drachms—is added and the trituration continued. By this means an ointment of mercury is left which equals 2 parts of mercury and 1 of lanolin. This is sometimes called strong gray ointment. For hypodermic injection, 3 parts of this gray ointment are added to 1 part of olive oil, or it may be still further diluted by adding olive oil in the proportion of half and half. Of this mixture 10 to 20 minims may be injected every second or third day.

---

## Reports on Therapeutic Progress.

---

### *GUAIACOL AS A TOPICAL APPLICATION IN THE TREATMENT OF ACUTE TONSILLITIS.*

RAYMOND (*Medical Record*, March 24, 1894), as the result of experience, found that the application of guaiacol is somewhat unpleasant and is attended with quite a little smarting, but as its duration is only from one to five minutes in most cases (although in some instances it lasted for several hours), the relief caused by the application more than overbalanced the pain. However, it is frequently no more painful than nitrate of silver or many other remedies commonly used, and possesses many advantages over them, the cardinal one being as a curative measure or as an abortifacient. It was thought that a thorough application of cocaine (ten-per-cent. solution) prior to the application of guaiacol would lessen the degree of smarting, but it seemed to aggravate it. The applications were made by means of a cotton swab dipped into pure guaiacol, and applied over the surface of the tonsils, care being taken to prevent it from getting into the larynx. To keep the throat moistened, troches of althea, or guaiac, or gargles were given. In every case where marked febrile symptoms were noted, the temperature was found to drop from one degree to normal within a few hours. In one case where it registered 103.5° F., it fell to normal in four hours.

In the superficial or lacunar variety the inflammation was terminated far more speedily than in the phlegmonous.

In a number of cases with a history of having had quinsy, and where every evidence of a re-

current attack was present, it was found that not more than two applications were necessary to abort the disease, and in many instances it did not last more than forty-eight hours, and in none did suppuration occur. In many cases where patients were unable to swallow without intense pain, they were able to do so within ten minutes. In a few patients suffering from a primary attack, swelling was seen to subside within a few hours.

#### THE VALUE OF GUAIACOL AS AN ANTI-PYRETIC.

THAYER, of Baltimore, contributes a valuable therapeutic summary on this topic to the *Medical News* of March 31, 1894, and concludes from the few experiments which he has made, and from a consideration of the results obtained by other observers, that we are perhaps justified in asserting that guaiacol applied to the skin is readily absorbed into the economy; that its application is followed in most instances of fever by a gradual reduction in temperature, which reaches its lowest point generally between three and four hours after the application; that this fall of temperature is almost always associated with disagreeably profuse sweating; at a variable period, usually a short time after the lowest point is reached, the temperature rises rapidly, generally in association with marked chilly sensations, if not with an actual chill; that a dose of more than 2 cubic centimetres is rarely advisable; that exactly similar results are produced by the absorption of guaiacol through any other channel (the rectum or the subcutaneous tissues); that the antipyretic action is exactly similar to that which has been previously observed to follow a corresponding use of creosote and carbolic acid; that, owing to the disagreeable effects of the immediate application of guaiacol (sweating and chilliness) and the weakening effects of the continued use, its employment as an antipyretic, as in the case of carbolic acid and creosote, will probably have but a limited application.

#### THE TREATMENT OF PREGNANCY COMPLICATED BY HEART-DISEASE.

SEARS (*Boston Medical and Surgical Journal*, March 15, 1894), in a paper with the above title, reaches the following conclusions:

1. That many women with valvular disease, even when it is situated at the mitral orifice, pass through repeated pregnancies without the development of serious symptoms, and at times

without suspecting that they are victims of such disease.

2. That miscarriages are very frequent, and the chances of the child's surviving more than a few years are doubtful. If the mother's condition during pregnancy has been serious, the probable fate of the child should take much more prominence in deciding the question of abortion.

3. That the necessity of inducing abortion is very apparent if grave symptoms have appeared during the early months or are present with an advancing lesion, or if there is a history of extreme danger in the preceding pregnancy.

4. That if the necessity for an abortion becomes apparent, the sooner it is done the better, while the fœtus is still small and the expulsive force chiefly furnished by the uterus.

5. That the hope that relief may be given when the case has become desperate by inducing abortion is delusive, as it is possible that it only increases the danger.

6. That marriage should be forbidden, except perhaps in very unusual cases, to women suffering from cardiac disease.

#### DEATH UNDER ETHYL BROMIDE.

KOCHLER (*Centralbl. f. Chir.*, No 2, 1894) reports an instance of death during the administration of ethyl bromide. The patient, a weak, though otherwise apparently healthy, woman, aged twenty-one, was about to be submitted to an operation for rectal fistula. The anæsthetic was given in small quantities with a mask. After a very transient and mild stage of excitement the heart's action suddenly ceased. The breathing continued for about half an hour, but, notwithstanding galvanism of the phrenic nerves, subcutaneous injections of ether, and injections of saline solution into the median basilic vein, the patient never rallied. There can be no doubt, the author thinks, that the fatal result in this case was due to cardiac paralysis. The air-passages remained quite free, and breathing persisted for some time after the cessation of the cardiac movements. There was no indication of any respiratory disturbance. The phrenic nerves ceased to react to the electric current between four and five minutes after the arrest of the heart's action. The anæsthetic, on careful examination, was found to be pure. Ethyl bromide, it is held, cannot be regarded as an absolutely safe anæsthetic. No fewer than five cases have been recorded in which death was the result of a careful administration of a pure preparation

of ethyl bromide. The result of the necropsy in the author's case confirmed the suspicions that had been suggested by the very sudden arrest of the circulation. The left side of the heart was contracted and empty, and the walls collapsed. The muscular structure showed signs of extreme fatty degeneration, being speckled and studded with white patches. The surface of the heart was covered with a thick layer of fat, extensions of which could be traced in the very thin muscular walls of the ventricles.—*British Medical Journal*, March 10, 1894.

#### HYPODERMIC INJECTIONS OF THIOSINAMIN VALUELESS IN TUBERCULOSIS OF LARYNX AND LUNGS.

SENDZIAK concludes a paper on this subject as follows:

Thiosinamin, subcutaneously applied, has in certain cases a positive influence upon the course of the tubercular process in the larynx.

Upon the tubercular process of the lungs thiosinamin seems not to have any positive influence.

Also upon the general condition in most cases this drug does not act satisfactorily.

In lupus of the nose, thiosinamin, like tuberculin, may, Hebra asserts, be applied with comparatively great advantage.

This drug seems not to produce general reaction, which, as is known, was the weak point of Koch's remedy; but it must be applied with certain precautions in tuberculosis of the lungs and larynx.

Finally, after making the above observations, the author arrived at the conviction that the results obtained by him with thiosinamin, subcutaneously applied, in tubercular diseases of the larynx and lungs, were not very encouraging, which disheartened him from further experiments with this drug.

In his opinion, thiosinamin, so warmly recommended by Hebra in laryngeal and pulmonary tuberculosis, will share the same lot as its antecedents, Koch's tuberculin, Klebs's tuberculocidin, and Liebreich's cantharidinate of potassium,—i.e., it will be lost in oblivion.

Agreeing with Hebra as to the appearance of local reaction in lupus, obtained by thiosinamin, Spiegler, in another paper, affirms that he did not discover any distinct therapeutic effects of this drug in this disease, and he was obliged to return to his former local treatment.—*Journal of Laryngology, Rhinology, and Otology*, March, 1894.

#### BENEFICIAL RESULTS OF SALICYLATE OF SODIUM IN INFANTILE TETANUS.

DRS. SOTOLONGO and LYNCH describe a case of tetanus in its initial state, occurring in a baby nine days old, and which in all probability arose through infection at the umbilicus. The mother was delivered by an ignorant midwife, and, as a result, suppuration at the umbilicus followed. The wound was treated with bichloride of mercury, iodoform, and antiseptic dressings, while internally the hydrate of chloral and the bromides were administered. The trismus was so pronounced that the child's mouth could hardly be forced open, and its food and medicine were given drop by drop. The improvement was hardly perceptible, and, fearing a fatal issue, the author decided to try the salicylate of sodium. Accordingly, 20 centigrammes (4 grains) were given in two portions after the first dose; the father gave the second powder at the end of the third hour. On the following day a notable improvement was perceptible, and the drug was continued. The baby made a complete recovery.—*Journal of Nervous and Mental Diseases*, March, 1894.

#### SULPHUR IN DIPHTHERIA.

BAÜMLER, of Freiburg, has for years employed sulphur in diphtheria. He was first induced to try it by the recommendation given to this local treatment by Professor von Liebermeister, in his lectures on special pathology and therapeutics, where he says, "As a local application, I generally use powdering with crude sublimed sulphur, by abundantly applying with a thick, soft camel's-hair brush the dry powder to the diseased mucous membrane. This powdering of the pharynx with sulphur is, according to circumstances, repeated every hour or every two hours, or only three or four times a day." On the strength of several years' experience, the writer entirely concurs with Professor Liebermeister's further remarks,—“I have the impression that by this treatment, when commenced early, I attain more than by any other which I had tried before, and that with these applications the cases, on an average, take a considerably more favorable course than without it.” Bäumler has repeatedly seen cases, in which gangrene of the uvula and part of the soft palate seemed unavoidable, take a favorable turn in a few days, the membranes becoming detached and the swelling going down, leaving much less loss of substance behind than was to be feared when first seeing

the case. With less extensive disease we could frequently notice the first effects of the application to consist in a somewhat increased injection (not congestion) of the mucous membrane on the borders of the exudation, the latter becoming more sharply defined at its edges after a few applications, and then beginning to get loose and be detached.

In the majority of fresh cases of diphtheritic sore throat, as well as of lacunar tonsillitis, two or three applications a day seemed sufficient, the patients in the mean time, when able, gargling with a weak solution of permanganate of potassium, and being subjected to such general treatment as the case required (cool baths or the wet sheet, or occasionally a dose of antipyrin when there was high pyrexia, and great care as to feeding by mouth, or, if necessary, by the rectum).

How the sulphur acts in these cases the writer is unable to say, and mentions that there seems to be no particular difference in the action of sublimed or precipitated sulphur. We are not aware that as yet any experiments have been made with regard to the action of sulphur on the particular bacteria which cause diphtheritic and other kinds of sore throats (Loeffler's bacilli and streptococcus chiefly). But while anxious for the scientific explanation of the facts so frequently observed, we need not delay making the experience gained more generally useful.

The action of this remedy being a merely local one, its principal field of usefulness will be in diphtheria of the fauces, where it can be applied directly and abundantly. The larynx also, and in certain cases the upper part of the trachea, may be reached by using a curved insufflator for blowing in the powder. But no effect can, of course, be expected when the disease extends into the bronchial tubes, or when the general blood-poisoning has gone beyond a certain degree, nor even locally, where extensive sloughing has already taken place in the throat, and when, in consequence thereof, rectal feeding is the only, and then mostly insufficient, means to prevent exhaustion.

The author is unable to say whether remedies which have more recently been recommended, such as pyoktanin or the peroxide of hydrogen, which has found such warm supporters in America, give even better results than the sulphur, as, especially in severe cases, he did not feel justified in foregoing the benefits of a remedy whose efficacy he had had ample personal experience of.—*British Medical Journal*, March 3, 1894.

#### MALAKINE: A NEW ANTISEPTIC.

According to the *Journal de Médecine de Paris* for February 25, 1894, this substance results from the combination of salicylic aldehyde and parphenetidine, and occurs in small, needle-like crystals of a clear yellow color, which are insoluble in water. As a result of his experiments, JACQUET, of Basel, finds that the drug produces a reduction of temperature, which, unlike that produced by antipyrin and acetanilide, comes on gradually. He found that in typhoid fever and in the fever of tuberculosis the drug exerts its best influence. After the administration of 15 grains the temperature began to fall in from one and a half to two hours after ingestion, and reached its full fall four to six hours afterwards. A repetition of the dose is followed by an increase of effect.

#### A NEW ANTINEURALGIC.

Under the name neurodine, the chemical name of which is acetyl-para-oxyphenylurethane, the *Journal de Médecine de Paris* states that this compound is useful for the relief of neuralgia, and that Von Mering recommends it in the dose of 15 to 20 grains as a succedaneum to phenacetine in painful affections of the head. The pain disappears in about half an hour after the drug is taken. The drug acts equally as an antipyretic, reducing the temperature from two to three degrees in the dose of 7 or 8 grains. The effect, however, is rapid, and is apt to be followed by cyanosis and sweating. It is best given in cachets.

#### ARSENIC AND CANCER.

Among the ingenious and plausible suggestions emanating from Mr. JONATHAN HUTCHINSON is the possibility of the evolution of epithelioma being facilitated by a long course of arsenic. In his well-known paper on the subject he alleged a number of instances in which there was certainly presumptive evidence of arsenic having thus favored the evolution of the cancerous outbreak. At a recent meeting of the Clinical Society *apropos* of a case of multiple epithelioma following a course of arsenic, he called attention to certain peculiar changes in the skin of the palms and soles which, in his opinion, indicate that it is time to desist from the administration of the drug,—viz., a furfuraceous thickening of the skin in those situations. We call attention to this statement in order that our readers may avail themselves of any and every opportunity of ascertaining how far the

suggestion is confirmed by clinical observation.—*Medical Press and Circular*, February 21, 1894.

#### THE EXTERNAL USE OF GUAIACOL.

In *La Province Médicale* for February 3 there is an article on this subject, of which the following is the substance: This drug, which was used by Sciolla and Bard, has for some time been employed as an antithermic. It consists in painting the greater part of the exterior wall of the thorax, and sometimes the forearms, with pure guaiacol. According to different authors, the doses are variable, ranging from 1 to 2 cubic centimetres up to 7 or 8. There is a difference of opinion as to the employment of this liquid. Sciolla, Bard, and other physicians use pure guaiacol, while others, like Desplats, mix it with glycerin or alcohol. In several cases of advanced phthisis a marked reduction of two degrees has been obtained by painting the entire surface of the front of the thorax with pure guaiacol. Unfortunately, the effects of this treatment are only temporary, not lasting more than three or four days. Sometimes, also, applications of this kind produce a marked rise in temperature,—in one case of two degrees. It is necessary, then, in making use of this procedure to ascertain the susceptibility of the patient, and to use at first small and then progressively large doses. There have been of late years interesting attempts in the employment of this procedure. Casasovici and Miron Sigalea have used guaiacol mixed with tincture of iodine, in the treatment of pleurisy, in the following proportion: Tincture of iodine, 385 grains; guaiacol, 75 grains. This quantity is used in a single application, and the diseased parts are thoroughly and extensively painted with it every night. These applications cause a considerable reduction of temperature, profuse perspiration, and an increased flow of urine, followed soon after by complete resorption. These results seem to have been obtained, particularly in one case, where there was abundant pleuritic effusion on the left side, in which tapping had not been followed by any relief, but had caused a considerable rise in temperature, by the application of iodized guaiacol, the fever disappearing in a few days and the effusion becoming resorbed.

M. Desplats has recently conceived the idea of applying guaiacol in the treatment of painful rheumatic inflammation of the joints, after having observed a case in which applications of guaiacol had been used with excellent results. He has used a mixture of equal parts of guaiacol

and pure glycerin. The joints were thoroughly painted with this mixture and afterwards covered with a dry dressing. In one case of acute rheumatism and in three others of arthritis deformans with sharp pains the results were excellent. The pain was completely subdued, and in the first case the patient recovered rapidly. This procedure has recently been employed in applying guaiacol for articular neuralgia of the shoulder, which was very painful, in a tuberculous patient, who experienced marked relief. It is easily employed, and not dangerous if the indications mentioned are conformed to.—*New York Medical Journal*, March 3, 1894.

#### THE ABORTIVE TREATMENT OF QUINSY.

In the February number of the *Annales des Maladies de l'Oreille, du Larynx, du Nez, et du Pharynx* there is an abstract of an article by M. Liégeois, published in the *Revue de Clinique et de Thérapeutique*. The author states that he has succeeded in aborting an attack of quinsy between the fourth and sixth days in six cases by means of combined local and general treatment. At the outset he cauterizes the tonsil once by painting it with a solution of 1 part of zinc chloride in 20 parts of glycerin. The eschar separates in forty-eight hours. After the cauterization, a drachm of salol is to be taken in the course of twelve hours. The salol acts as an intestinal antiseptic, an antipyretic, and an analgesic. [This treatment certainly is heroic and the dose of salol dangerously large.—ED.]—*New York Medical Journal*, March 3, 1894.

#### NOTES ON THE PHYSIOLOGICAL ACTION OF OZONE PREPARATIONS.

In the *Medical Record* of March 3, 1894, DR. THOMPSON, of New York, contributes an interesting article on this subject. The conclusions at which he arrives respecting the effect of ozonizing agents when given by the stomach or injected directly into the intestine or the blood, after a series of carefully carried out laboratory experiments, are as follows:

1. When injected in the circulation in full strength—i.e., fifteen volumes per cent.—they have a very destructive action upon the blood, thereby ultimately having the effect of reducing rather than of oxidizing agents for the tissues.
2. Acting through the stomach or intestine, they may similarly affect the blood, and in addition they destroy the gastric and intestinal mucous membrane.
3. Given in medicinal doses by the stomach,

their only benefit, if any, consists purely in their local action in the alimentary canal, in possibly preventing abnormal fermentations.

4. If so used, care should be exercised, owing to the great variability in strength of different preparations.

5. Ozone is of no real value to the tissues, whether inhaled or drunk in fluid preparations, and it may be exceedingly harmful.

[These results are of interest in view of the fact that many manufacturers of nostrums purporting to contain ozone claim that these substances give off oxygen or ozone to the body when taken internally. Most of these claims are equivalent in value, as proved by Dr. Thompson, to the claims of the manufacturers of electric belts.—Ed.]

#### THE USE OF DIGITALIS IN CHILDREN.

COMBY contributes an article on this topic to *La Médecine Moderne* for February 17, 1894. He points out that digitalis, in the eye of the laity and of the medical profession, is a remedy *par excellence* for maladies of the heart, and finds its chief application in the treatment of cardiac insufficiency. The other remedies which can be considered as adjuvants to digitalis in these circumstances are caffeine, sparteine, kola, and strophanthus. Of the indications and contra-indications governing the dosage and prescription of digitalis to children he speaks as follows:

Children are exceedingly susceptible to the action of this drug. There are several indications, nevertheless, for its employment. First, in those diseases of the heart in which there is insufficiency and cardiac feebleness, either congenital or acquired, or in those instances in which the action of the heart is too rapid or irregular. The drug under these circumstances acts as a tonic to the heart, as quinine does to the general system. Naturally, it does best in mitral insufficiency and least well in aortic regurgitation. It is indicated in those cases where compensatory hypertrophy is lacking. He thinks it is also of value in acute endo- and pericarditis. Secondly, digitalis is indicated in certain disorders of the respiratory apparatus, as, for example, pleurisy and hydrothorax, where it favors absorption of the exudate by its diuretic influence. In pneumonia it tends to reduce temperature, and it is claimed to have a slight jugulating power.

Simon believes that digitalis is of value in the treatment of irritability of the heart, and also that because of its steady influence over

the circulation it may be employed with advantage in hæmoptysis.

As to whether digitalis is of value in renal troubles in children, Comby thinks that during the acute stages of the malady digitalis should not be employed and a milk diet solely resorted to. On the other hand, in chronic renal disease with passive congestion, with or without anasarca, the employment of digitalis is a measure often of advantage and without danger. Should there, however, be hypertrophy of the left ventricle, digitalis is contra-indicated. In acute infectious diseases digitalis is indicated only in the presence of complications involving the organs already named. It should also be remembered that it possesses some antipyretic influence. In the treatment of disease of the nervous system, through its sedative influence, digitalis is believed to be of value in epilepsy and in mania, the dose under these circumstances being as much as 30 drops of the tincture to a child of fourteen years. In regard to the prescription of digitalis, Comby directs as follows:

R Powdered digitalis leaves, gr. ii;  
Distilled water, ʒxii;  
Syrup, ʒxii.

Make an infusion, and administer a teaspoonful to a dessertspoonful every two hours to a child of ten years.

Or, for a child of the same age:

R Powdered digitalis, gr. i;  
Extract of digitalis, gr. i;  
Excipient and glycerin, a sufficient quantity.

Make into one pill, and administer such a pill three times a day.

[This is certainly a very large dose of digitalis, even for an adult.—Ed.]

#### RESEARCHES REGARDING HYDROGEN PEROXIDE SOLUTION.

SQUIBB publishes (*Ephemeris*, January, 1894) an elaborate account of experiments performed with hydrogen peroxide solution, with a view to ascertaining the best mode of preparation and to determine its keeping qualities.

It was found by these experiments that at ordinary temperatures and with ordinary agitation the dioxide in the solution is likely to be all practically decomposed in about eight weeks' time. Pressure exerted no discoverable influence on this change. Weak bottles may burst if securely corked, but the packing bottle of ordinary strength is able to withstand all the pressure developed from its contents.

The author endeavored to find a preservative

it when he awakes with a heaviness in the early morning, instead of turning over and going to sleep again. The quantity necessarily varies with different individuals and with the severity of the headache, but 30 or 35 grains of bromide of potassium with 5 to 15 grains of salicylate of sodium, in half a tumblerful of water, may be looked upon as an average dose. If the patient feels the irritability indicative of the approaching headache overnight, or if he should have the excessive brightness which is the precursor of headache in others, he should take this dose at bedtime, and will very probably awake without the headache. If, in spite of it, he should awake with a heaviness in his head between four and six, he should repeat the dose, or should take it for the first time if no indication of headache has been felt the night before, but the heaviness has come on during sleep. He will then probably turn round, fall asleep again, and awake without the headache. If, however, there should be either heaviness or headache on awakening about 7 A.M., a third dose should be taken. The writer has tried the bromide and the salicylate separately, but he does not think they act nearly so well as when taken in combination. Ten days before writing the present article the writer received a letter from a physician who was suffering from a very severe headache after influenza. He had tried antipyrin, which had relieved it for the time, but had to be continued every twenty-four hours. He had also tried chloride of ammonium and bromide of ammonium with the same result. He was advised to try 20 grains of salicylate of sodium with 40 of bromide of potassium in half a tumblerful of water, and after four doses of the mixture the pain subsided.

#### PRESCRIPTIONS.

Application for chronic pharyngitis:

R Iod., gr. vi;  
Potassii iodidi, gr. xii;  
Mentholi, ʒi;  
Glycerini, q. s. ad ʒi. M.

Apply with a camel's-hair brush twice or thrice daily.

Useful in bronchitic asthma:

R Potassii iodidi, ʒii;  
Ammon. carb., ʒi;  
Tinct. lobeliae, ʒii;  
Sp. chloroformi, ʒiv;  
Vin. ipecac., ʒi;  
Infus. senegae, q. s. ad ʒvi. M.

A tablespoonful in a wineglassful of water every four

Incontinence of urine:

R Tincturae belladonnae,  
Tincturae cubebae, of each, ʒii;  
Tincturae nucis vomicae,  
Tincturae rhois aromaticae, of each, ʒi;  
Tincturae cascariillae, ʒii.

12 drops at bedtime for a child from seven to ten years.

The removal of warts:

R Hydrarg. bichlor., gr. v;  
Acid. salicyl., ʒi;  
Collodion, ʒi. M.

This is applied every day, the upper crust of the previous application being removed before a fresh one is made. Usually after four applications the wart becomes so softened that gentle friction will remove it painlessly. If a further dressing is required, a five-per-cent. salicylic-lanolin ointment is all that is necessary.

*Ozæna*.—Dr. Stein obtains in ozæna most remarkable results from painting the nasal fossæ with a solution of trichloroacetic acid. The painting is done by means of a piece of cotton-wool steeped in a solution (one-tenth per cent.) and fixed on the point of a flexible wire. The operation is done three times daily for the first few days and then once a day. The strength of the solution is gradually increased.

*Asthma*.—The following will be found most useful in this distressing complaint:

R Chloralis,  
Potassii iodidi, of each, ʒss;  
Syrup of oranges, ʒvi;  
Water, ʒvi.  
2 to 5 tablespoonfuls a day.

—*Medical Press and Circular*, February 21, 1894.

#### THE TREATMENT OF PERITONITIS.

During the last few weeks, MR. FREDERICK TREVES, of London, has delivered a series of valuable lectures on peritonitis, which have appeared in part in the *Medical Press and Circular*. They form the best statement of facts about the disease that we know of. Part of his last lecture was devoted to treatment, and every word of it seems so useful to the practising doctor that we reproduce it for our readers, lest, in an attempt to condense it, its value be lost.

In considering the treatment of any grave affection, it is well to recollect that certain of the so-called symptoms of a disease are not gross evidences of a disturbing evil within the

body, but are rather the natural expression on the part of the organism of an attempt to rid itself of a trouble. Many symptoms are, in fact, curative acts, and are the measures of a natural treatment and not the mere purposeless signs of an unnatural disturbance.

In peritonitis, the exhaustion, the rigidity of the belly-wall, the pain, the vomiting, and the not infrequent sense that the bowel needs to be emptied of flatus, would suggest the recommendation of absolute rest, of attempts to relieve pain, of starvation, and, under certain circumstances, of means to relieve the intestine. If, in contemplating a patient with peritonitis, one could regard his more conspicuous symptoms as natural attempts to afford relief, they would appear to be in the direction of securing quiet within the inclosure of the abdomen, and of effecting an evacuation of the alimentary canal.

In the account which follows of the treatment of peritonitis, this suggestion from the therapeutics of nature is not disregarded.

1. *Rest*.—Absolute rest in the recumbent position appears to be the first obvious indication. The knees may be flexed over a pillow to lessen the tension on the abdominal walls and to favor the patient's instinct to assume that posture. The upper part of the chest and the ever-restless upper limbs should be protected by a woollen jacket, and no reasonable restraint offered to the patient's inclination to hold the hands above the head. This favorite posture, by acting upon the lower parts of the thoracic wall, assists also in diminishing the tension within the abdomen. It is cruel to insist that the hands should be kept beneath the bedclothes. The state of misery in peritonitis is acute enough without being increased by purposeless and rigid formulæ. Cold hands do not cause death, but as on exposure they tend to become cold, they should be covered up. The wretchedness of restlessness has a natural relief in little movements.

2. *Feeding*.—The old rule of eighty years ago of giving as little food as possible by the mouth cannot be improved upon. The stomach is not in a condition to receive nourishment, and what is taken usually remains unutilized and is returned unchanged. The practice sometimes met with of laboriously plying the patient with teaspoonfuls of this or that meat extract recalls the legend of the Daïdes, who spent their energies in pouring water into pitchers without bottoms.

In the matter of feeding there are two extremes to be avoided. The first is the rigid, unreasoning, and often needlessly cruel prohibition of any kind of food by the mouth;

and the second is the reckless and intemperate use of ice or iced fluids.

Thirst is often a most terrible symptom in peritonitis. It is not always quite relieved—at first, at least—by rectal injections. The patient is ready to give his life for a drop of cold water. If he takes it, he is sick, but he is much relieved. This little indulgence does not introduce anew the symptoms of vomiting. It is there, but it is latent, and the drop of cold water only makes it evident. The patient will not die of vomiting, and simply because a rigid exclusion of all fluid by the mouth does not render the symptom apparent, it does not render it non-existing. The man would sooner vomit than endure this thirst. Very often great relief is given by allowing a fairly copious draught of fluid, which is soon rejected, and which—as it were, by washing out the stomach—leaves the patient for a while infinitely comforted. On the other hand, the perpetual sucking of ice is as bad as the perpetual teaspoonful of useless jelly of decomposable meat-juice. The filling of the stomach with iced water does undoubtedly add to the general depression of the patient, especially when vomiting has been brought into abeyance by morphine.

The right course appears to lie between these two extremes. There should be no rigid formula except this: let the patient take as little food as possible by the mouth. If there be a raging thirst, let him have a little ice,—and very little suffices,—or a little iced milk and soda-water; or if, as is common, the inclination lies to something warm, let him take a few teaspoonfuls of hot water or of weak tea made hot, or, of beef-tea at a like temperature. It is not the nourishment that is needed, but some fluid in the stomach.

It is better, within reasonable limits, to be guided by the patient's own instincts than by a blind formula founded upon a doubtful physiology.

3. *Opium*.—Here, again, the old practice appears to be the best. Give as little opium as possible. In the early stages of acute peritonitis, and especially in the perforative forms and in those depending upon appendix troubles, morphine, in the form of a hypodermic, is absolutely necessary. In the worst instances, it may certainly avert death from shock. Under its influence the patient revives and the more intense symptoms become greatly modified. Morphine should never become a feature in the routine care of peritonitis: it masks the symptoms, hinders the natural process of cure, and hampers treatment. The indication for it

is actual pain, and not mere restlessness and misery. In the really septic forms but very little morphine is called for, and often none at all. Its evil effect in the after-treatment of cases of abdominal section has been amply demonstrated. In quite hopeless cases there can be no objection to its freer employment, but in other instances the administration and the dose of the drug must be sanctioned and measured by the one symptom,—pain.

4. *Aperients*.—At the commencement of the century the use of aperients was a necessary element in the routine treatment of peritonitis. By aperient treatment may be understood the obtaining of an action of the bowels by either drugs or enemata. After a certain number of years the practice altered, and the dictum went forth that when any signs of peritonitis were present, aperients were to be absolutely forbidden.

Within the last few years the more ancient method has been revived, but it has been revived with very radical modifications. To Mr. Lawson Tait the profession is indebted for this return to an almost forgotten practice, and, above all, for the employment of that practice with the new element of discrimination. Mr. Tait's measure has been frequently spoken of as "the treatment of peritonitis by aperients," and it has been assumed by some—and probably with disaster—that a purgative is necessary in every case of peritoneal inflammation. Mr. Tait's precise words on this subject are as follows: "I have never said that the purgative treatment will cure peritonitis, for peritonitis, once it is completely established, is a practically incurable disease and almost uniformly fatal."

It is on this very point that the centre of the position with regard to this treatment turns. Aperients can never be adopted in the routine treatment of peritonitis. In the larger proportion of cases this measure is entirely useless, and in the great series of the septic forms it is more or less impracticable.

It is a fact that the most successful treatment of acute obstruction of a certain grade is that which provides for a thorough evacuation of the loaded gut. A blindly-executed enterotomy, with an utter ignoring of the cause of the obstruction, has been attended by better results than have operations in which the agent of the obstruction has been discovered after elaborate search, and has been satisfactorily dealt with. This treatment of acute obstruction by the evacuation of the bowel before all things we owe to Benjamin Travers, the father of intestinal surgery. In cases of strangulation

of a certain degree he insisted that the bowel should be cut into and emptied, even after the obstructing band has been removed. He considered that the operation was not complete until this had been done. He urged that safety was only to be obtained by an evacuation of the gut, and he supported his views by numerous cases and experiments.

Another illustration of these self-same points is afforded by perityphlitis. In a previous section of these lectures it was shown that those cases of perityphlitis in which there is diarrhoea, or in which the bowels act naturally or under the influence of aperients, are attended with a much lower mortality than are the cases in which constipation is marked. The writer is convinced from his experience of the value of the aperient treatment in the earliest stages of these cases, and of the pursuit of the same measure throughout in selected instances. In some cases, however, nothing within reason will bring about an action of the bowels. When once general peritonitis has established itself, an aperient is without avail.

5. *Bloodletting*.—This measure of treatment may with advantage be more extensively employed. It is no longer likely to be used in the unreasoning and mechanical fashion of by-gone days. In robust forms of localized peritonitis, bloodletting is attended with admirable results. In perityphlitis the application of half a dozen leeches often acts with magical effect. In the older accounts of the treatment of peritonitis by bleeding, no good appears to have followed in cases in which the inflammation was diffused, except, perhaps, in some examples due to injury. On theoretical grounds this is precisely what would be expected.

6. *Operative Measures*.—These are represented by incision and drainage, with or without irrigation. This treatment must be considered, as it applies to peritonitis, under two entirely different aspects. In one series of cases there is vigorous, well-defined inflammation, the local symptoms are marked, pus is produced and may be considerable in amount, and the exudation is more or less clearly localized. In the other series of cases the peritonitis is diffused, the constitutional symptoms are more prominent than the local ones, the changes in the serous membrane—so far as evidence of inflammation is concerned—are comparatively slight, and are out of proportion to the general disturbance.

In the first series of cases surgical interference by incision and drainage ranks with the procedure of evacuating a large abscess.

In the second series the cut into the ab-

domen and the subsequent flushing out or drainage are to be compared with the washing out of the stomach after an active poison has been swallowed.

The operative treatment of suppurative peritonitis, especially when the effusion is localized, has been remarkably successful. Records of the operation extend back into the eighteenth century, and all that modern surgery can lay claim to is the application of the treatment with greater boldness, with greater frequency, and with infinitely less delay.

The operative treatment of general diffused non-tuberculous peritonitis has so far no record to boast of and little progress to chronicle. It is doubtful whether a single human life has been saved by surgical interference in a genuine case of peritoneal toxæmia. Surgical treatment has been most discouraging in acute peritonitis following upon gangrenous hernia, upon operation, and upon puerperal infection. It has met with but little better results in cases of perforation in which the serous inflammation has been well established.

As to the actual mode of operating adapted for the different varieties of peritonitis, attention should be drawn to the following points. In all cases it is to be assumed that the skin over the operation area is cleansed and prepared in a suitable way, and that the surgeon adopts those measures which students in their examination papers are so fond of describing as "strict antiseptic precautions."

In cases of localized purulent peritonitis an incision should be made into the collection by the most direct route. When the pus has escaped, a rubber drainage-tube of suitable size and with stiff fenestrated walls should be passed to the bottom of the cavity. A dressing of some absorbent material, such as Tillmann's papers, sal alembroth, or cyanide gauze, is then applied. No advantage follows fuller evacuation of the pus by squeezing or the immediate irrigation of the cavity, and distinct harm may be done by scraping the wall of the inclosure, by persistent searching for a diseased appendix or other cause of the trouble, and by stuffing the exposed space with a considerable quantity of gauze.

At the end of twenty-four or thirty-six hours the irrigation of the cavity may be commenced and continued twice daily, and now and then a little iodoform emulsion may be introduced.

In some examples of perityphlitis a well-encapsulated collection of pus is not exposed, but the knife enters into an ill-defined district containing a variable quantity of thin, greenish,

and often offensive matter, which appears to saturate the tissues. In such circumstances a drain composed of strips of iodoform gauze, which are carefully introduced into the lowest accessible recesses of the region, is of advantage.

In cases of generalized peritonitis the procedure adopted must obviously depend upon the cause and degree of the trouble. If the exudation be serous, it will suffice if the fluid be evacuated, if the peritoneal cavity be gently dried in its most dependent parts by means of gauze sponges, and if the abdomen be closed without drainage.

When the exudation is sero-purulent, it is in many cases desirable that the cavity be irrigated. The fluid which appears to be best suited for this purpose is a .6-per-cent. salt solution made warm. After the washing, the depths of the peritoneal cavity are dried, so far as is possible, with sponges, iodoform powder is very freely dusted over the portion of the serous membrane most involved, a long, rubber, fenestrated drainage-tube is introduced, and the abdominal wound is closed. Any treatment directed against the cause of the peritonitis will be independent of these measures.

There are cases in which the peritonitis is more plastic in character. The intestines are found to be matted together with grayish lymph, which may be present in considerable quantity. The breaking down of these adhesions causes no little amount of bleeding, and such a step is evidently destructive of a certain desirable process of repair. Still, in order to search for the cause of the peritonitis, assuming such search to be indicated, and to set free an amount of exudation which is imprisoned between the attached coils, this freeing of adhesions must be to a certain very limited extent carried out. There will probably be a sero-purulent exudation in the belly cavity, and the gentlest movements of the fingers among the recently attached intestines will set free more fluid, which will be probably less opaque. A clump of adherent intestines will often cover and protect a perforation, and the ubiquitous fingers will many times close such an opening with more speed and security than are provided by any system of suturing.

As the surgeon, therefore, reaches what appears to be the starting-point of the peritonitis, he must proceed with the utmost caution, and be not only prepared, but rather inclined, to leave the actual *fons et origo mali* undemonstrated. The main purpose of the operation is to allow a noxious exudation to escape, and, if

possible, to free the peritoneum of the cause of its trouble. In the class of cases now under discussion, a perforation will be very often the starting-point of the peritonitis; the lapse of time and the plastic character of the inflammation afford evidence that the perforation is, for the time being, closed. If the operator can rid the serous cavity of the effects of the perforation, he may often leave the breach itself to be dealt with by natural means. The wisdom of doing no more than is necessary, or as little as is obvious, is well illustrated by these cases.

*Irrigation.*—Mere blood is better removed from the peritoneal cavity by sponging than by irrigation. If the operation area be well circumscribed, by sponges, if the shoulders be raised so that blood will reach the more dependent tracts, and if a sponge be introduced into the pelvis at an early stage of the procedure, there is little trouble with blood-clot. Coagulated blood is certainly very much more easily and certainly removed by means of gauze sponges than by a stream of water. The same observations apply to what may be termed healthy cyst contents, to fluid from hydatids, to bile, and to matter escaping from the stomach or intestine. With careful plugging and a watchful use of sponges a wide-spread extravasation is uncommon. If it does take place, the gauze can usually reach it. Irrigation would possibly have the effect of spreading the noxious fluid—as, for example, intestinal matters—over a still wider area. It may be said, therefore, that if certain precautions be taken, the cleansing of the peritoneal sac may be best and most safely accomplished by dry sponging.

If there be a considerable outpouring of such a material as putrid pus, or if there be a copious escape of gut contents, as from the giving way of a distended bowel above a point of obstruction, then it may be better that the whole peritoneal cavity be irrigated. In such a case the extravasated fluid and its wide distribution would render its complete removal by sponging difficult.

This irrigation is best conducted by the following means. The fluid used is a sterile .6-per-cent. salt solution at blood-heat. It is introduced at low pressure, but in a wide stream. The irrigating-tube is of soft rubber and may have a diameter of three-fourths of an inch. The tube itself is introduced into the belly cavity. The flow through it can be regulated by a clip. Any form of rigid nozzle is to be most strongly condemned. The solution should flow gently into the abdomen. The peritoneal cavity is to be flooded and not to be scoured out with a violent stream of water, which hisses

and rushes from a vulcanite nozzle as from a miniature fire-hose.

When the belly cavity is quite full of fluid, the surgeon's hand—which is already in position—is moved to and fro among the intestines with great gentleness. The coils of bowel are thus rinsed. By a movement of the hand and by pressure here and there, the fluid overflows from the wound and is replaced by the steady stream.

As the water which escapes becomes clear, the upper end of the operation-table is raised, so that the shoulders are much elevated, and then little has to be done but to wash out the most dependent parts, including especially the pelvis, and to allow the upper parts to drain. Finally, what fluid remains in the pelvis is removed with sponges, and a sponge in a holder is retained in the bottom of the pelvis during the introduction of the stitches, and only withdrawn at the last moment.

*Drainage.*—It will be allowed by most that drainage is necessary when either an actually noxious material is left in the peritoneal cavity or when it is assumed that an extensive effusion will follow upon the laparotomy. Considerable differences of opinion must exist as to what constitutes, either in substance or in amount, a noxious material, and also to what extent a possible effusion is to be met by drainage.

A stout rubber drainage-tube of large size and well fenestrated, passed into the midst of the area which is the most disturbed, appears in most cases to answer all reasonable purposes. It is not suited for most tuberculous cases. It must be assumed that the surgeon has no objection after the operation to frequent and perhaps extensive changes in the patient's position for the purpose of assisting the process of drainage. The author has seen no harm arise from a liberal fulfilment of this object. In certain instances, some of which have been indicated, a gauze drain appears to be better adapted for the case than a rubber one. This drain is simply composed of a long strand of iodoform gauze about one and a half inches wide and some five to six layers thick. It appears to have been first advocated by Bardenheuer. In a case of purulent peritonitis, Jalaguier has passed these strands of gauze in all directions among the intestinal coils from the diaphragm to the pelvis with good result.

A like proceeding in like cases is advocated by Steinthal.

The great objections to the iodoform drains are these: They may induce symptoms of poisoning if very extensively employed, they are most difficult to remove unless there be a free

discharge, and their use is apt to be followed by ventral hernia.

Some surgeons, either to supplement or to replace drainage, allow the wound to gape, or support it merely by a few quite loose sutures. This measure has been especially advocated in the treatment of perforative purulent peritonitis.

In conclusion, it only remains to be said that the surgical treatment of peritonitis has not yet reached a position which is either satisfactory or secure. There has been no lack of boldness in the measures used and little sense of discouragement at the results obtained. Surgical enterprise has been directed against effects and against damage done, rather than against causes and the beginnings of evil. The surgeon holds the same position in regard to peritonitis which was held some thirty years ago in regard to wounds and more accessible forms of inflammation. At that time he dealt only with the consequences of pathological wrongdoing, just as now he concerns himself with the prevention of troubles which he has learned to control. Peritonitis will be more successfully treated when measures can be directed against the sowing of the wind rather than, as now, against the curbing of the whirlwind.

#### THE TREATMENT OF BRONCHITIS.

In *La Tribune Médicale* for February 1, 1894, there is an article upon the treatment of bronchitis and tracheitis. In the treatment of the latter, rest is required in a room of moderate temperature, hot drinks are to be given with small doses of syrup of tolu and mild alcoholic stimulation. In addition, every two or three hours, two teaspoonfuls of the following mixture may be used:

R Tincture of aconite, gtt. xxx;  
Syrup of narceine, ℥i;  
Cherry-laurel water, ℥iv;  
Peppermint-water, ℥iii.

At the same time it is well to paint the chest about the area of the episternal notch with tincture of iodine.

In the treatment of acute bronchitis in the early stages, when there is hyperæmia and fever with cough without expectoration, first rest in bed with sweating, the administration of hot drinks which may contain alcoholic stimulants, the application over the chest of mild counter-irritants. For the stage in which expectoration is just beginning and fever is still present, kermes mineral, grains seven, and syrup, four ounces, a teaspoonful every two or three hours.

At night, for the relief of cough, small doses of chloral and morphine in simple syrup, which are placed in milk at the moment of taking, may be administered. For the treatment of chronic bronchitis it is well to employ a teaspoonful of cod-liver oil with creosote, and to administer after each meal a mixture composed of,—

R Arsenate of sodium, gr. i;  
Iodide of sodium, ℥ii;  
Water, ℥viii.  
Tablespoonful three times a day.

Or,

R Terpene,  
Eucalyptol, of each, gr. iii.

To be placed in a capsule and taken three times a day.

From a hygienic point of view, the patient suffering from chronic bronchitis should sponge the body every morning with warm water and alcohol, and afterwards use vigorous friction of the skin. He should abstain from tobacco. Should the chronic bronchitis be fetid, it is wise to use every two hours the following solution by inhalation:

R Eucalyptol, ℥i;  
Ninety-per-cent. alcohol, ℥iii;  
Water, ℥vi.

Place this in an inhaler and draw in the air impregnated with the vapor of the medication. At the same time the following pill may be administered:

R Creosote,  
Terpene,  
Iodoform, of each, gr. i.  
Take this pill three times a day.

#### TREATMENT OF APOPLEXY.

In *L'Union Médicale* for March 3, 1894, is an article in which the following advice is given. At the time of the attack there should be applied counter-irritation, in the form of mustard sinapisms to the lower extremities, and should the face be flushed and the arterial pressure high, and the patient robust, copious venesection to the amount of a pint should be resorted to. Should these conditions not exist, and there be evidence of very great arterial sclerosis, the physician may have to be content with the withdrawal of a small quantity of blood in the neighborhood of the mastoid. At the same time it is well to administer a laxative injection, which may be composed of fluid extract of senna, sulphate of sodium, and water, in the proportion of one drachm of fluid extract of senna, six drachms of the sulphate of sodium,

and enough water to make a pint. The efficacy of this injection may be increased by the addition of oil or glycerin. Should the respiratory function become disordered and the Cheyne-Stokes phenomenon appear, hypodermic injections of caffeine, ether, or camphorated oil should be employed. For the purpose of preventing future attacks or the first attack, it is suggested that patients who have atheromatous vessels should take moderate exercise each day, should rest after eating, and only take those articles of diet which are easily digested. The following mixture may also be administered:

R Iodide of potassium,  $\text{ʒiii}$ ;  
Bromide of potassium,  $\text{ʒiii}$ ;  
Distilled water,  $\text{ʒiv}$ .  
1 or 2 tablespoonfuls each day in milk.

Should there be indications that the cerebral trouble depends upon syphilis for its existence, a mixed treatment must be actively employed. Mercurial inunctions should be resorted to daily, using from 1 to 2 drachms of mercurial ointment each time. The iodide of potassium may be given in the dose of 1 or 2 drachms a day, divided doses, given in milk.

#### THE ACTION OF DUBOISINE UPON THE NUTRITIVE PROCESSES.

In a further study of the action of duboisine as a therapeutic agent, E. MARANDON DE MONTYEL (*Bull. de Thérapeutique*, February 28, 1894) publishes the details of twenty-five cases of mental disease in which the drug was employed. According to the results obtained, duboisine, though possessing good hypnotic and excellent sedative virtues, exercises untoward effects, such as *habitus*, gastro-intestinal disturbances, cardiac weakness, and malassimilation. The author formulates the following conclusions:

1. Duboisine has undoubtedly exercised on the subjects observed an action manifested in a faulty nutrition.

2. This deleterious action on nutrition has been produced independently of the gastro-intestinal troubles that the drug may cause; because, when given after meals, in the majority of cases, especially upon those cases of general paralysis and lypemaniacs, the administration of the drug, notwithstanding the integrity of the digestive tube, has been followed by the same deleterious action upon nutrition.

3. This action, other things being equal, is aggravated by disorders of digestion; but it occurs in those subjects that have never suffered from such troubles as well as in those

who are victims of gastro-intestinal affections, a proof that the action is independent of these disturbances.

4. This malassimilation under the action of duboisine seems to occur in connection with other disturbances, such as slowness of the circulation, and particularly a rise of the bodily temperature.

5. It is absolutely necessary, in order to combat this deleterious action of duboisine upon nutrition, to associate the drug with a tonic reconstructive *régime*. The medicament, therefore, should be given with caution to patients of feeble constitution, especially in those diseases characterized by decided nutritive deterioration, and in all these cases the employment of the remedy should not be prolonged.

6. General paralytics are the ones who suffer the least and the most from this peculiar action of duboisine; they furnish the greatest number of those that escape the action; and yet, on the other hand, of all demented patients those suffering from disorders of nutrition are the ones to exhibit the greatest loss of bodily weight.

7. All lypemaniacs, without exception, are susceptible to malassimilation from the action of duboisine, and this malassimilation, even after the administration of the drug has been suspended, continues and becomes more difficult to combat than in the case of general paralytics or those suffering from simple dementia. Therefore, although the loss of weight is not as decided as in cases of general paralysis, it may be said that the action of duboisine upon nutrition is manifested more particularly in cases of lypemania, and to a minimum degree in cases of simple mania.

8. In the large majority of cases the suspension of the drug is the beginning of a return of the patients to their original bodily weight, but, notwithstanding this, the mental excitement returns, placing the patients in much less favorable conditions. All this seems to prove that the deleterious changes produced in the nutritive processes have been the result of the action of the drug.

9. The subcutaneous injection of duboisine, even in doses of 4 milligrammes, and continued for a long time, never causes local troubles, neither in general paralytics nor in vesanic patients; quite large amounts of duboisine have been administered in a certain number of epileptics.

#### ERGOT IN THE TREATMENT OF PERIODIC NEURALGIA.

DR. THOMSON, of New York, reports in the *Medical Record* of March 17, 1894, four cases

of very severe periodic neuralgia in which the administration of ergot was followed by the most pleasing results after ordinary anti-neuralgic remedies had failed. He administers the fluid extract of ergot combined with an equal quantity of the elixir of cinchona, the latter ingredient being added to prevent nausea. Two teaspoonfuls of this mixture are to be taken in water as soon as the premonitory symptoms of headache are noticed, and the patient is directed to lie down and keep very quiet. If no relief follows in an hour, another dose may be given, and in another hour still another dose. Should the patient vomit the drug, it may be given as a rectal injection in two ounces of water. Careful attention to the condition of the alimentary canal is necessary between the attacks.

#### *BROMIDE OF ETHYL AND CHLOROFORM NARCOSIS.*

PROFESSOR PAWLOFF, in discussing the narcosis resulting from bromide of ethyl and chloroform, reached the following conclusions:

1. The narcosis comes on in a relatively shorter time,—about two minutes,—and the patient does not pass through a stage of excitation.
2. It requires a very small amount of bromide of ethyl—about five grammes—to bring about full anæsthesia.
3. The narcosis is not attended by any disagreeable manifestations.
4. A small amount of chloroform is needed to keep the narcosis up.
5. There follow no bad after-effects.

About 16 grammes of the chloroform is required to keep up the narcosis for fifteen minutes.—*Medical Record*, March 17, 1894.

#### *THE TREATMENT OF URÆMIA.*

In the *New York Medical Record* for March 17, 1894, DR. BEVERLY ROBINSON contributes a valuable paper upon this topic, in which he reviews the various therapeutic resources for the combating of this condition.

After mentioning the value of cardiac stimulants, of diaphoretics, and of the external application of heat, he strongly urges the employment of venesection during the presence of convulsions or when they are imminent, and states that these manifestations will sometimes disappear even while the abstraction of blood is going on. In strong, robust patients he suggests the withdrawal of from twelve to twenty ounces of blood. He believes that many lives are saved by this measure, and cites

one case in which the most favorable results followed this method of treatment.

The patient, who was found unconscious in the street, and who had a uræmic convulsion on the way to the hospital, was profusely bled to the extent of two pints. Immediately after the bleeding, saline transfusion of two quarts of freshly-made salt solution was performed, using the opening in the vein from which the blood had been drawn. The injection seemed to work like a charm, for no sooner was it terminated than the patient's limbs began to move, his face appeared normal, and twenty minutes after the transfusion the patient was able to speak clearly and to remember events which occurred before his attack. Dr. Robinson therefore believes that, wherever it is possible, copious venesection, followed by intravenous injections of saline solutions, or of hypodermoclysis, should be resorted to, and if these are not possible, that enteroclysis be used. Should the patient be apparently moribund and collapsed, he may require hypodermic stimulation with extract of coca, strychnine, or ether. The preparation of coca which he employs for this purpose is prepared in the following manner: To four ounces of the fluid extract of coca add one ounce of glycerin, heat upon a water-bath until all alcohol has been driven off, and then add sufficient water to make the product measure two fluidounces. For the relief of the convulsions, before venesection can be resorted to, chloroform may be employed. The use of pilocarpine for the production of sweat he regards with suspicion.

In the discussion of Dr. Robinson's paper, Dr. Peabody strongly recommended urethane for the treatment of the convulsions. The drug is to be given by subcutaneous injection, and as it is a harmless remedy and easily absorbed and quite unirritating and painless, he thinks it should be frequently employed. His statement was corroborated by Dr. Kinnicut, who advises that the drug be given in very large doses, amounting to three or four hundred grains in twenty-four hours. Dr. Kinnicut thought that urethane would control almost all forms of convulsions after other remedies had failed.

#### *THE PREVENTION OF CRACKED NIPPLES.*

The *Lancet's* Paris correspondent says, "The direct relation of mammary abscess occurring during the period of suckling and excoriations of the nipple is now fully admitted. Many mothers object to suckling their infants on account of the dread of this complication. Artificial feeding with its frequent failures is then

resorted to, and the child suffers. Antiseptic washing of the nipples has greatly diminished the frequency of abscess of the breast, but cracked nipples continue to be of common occurrence. For the last ten years Professor Pinard has been in the habit of advising nurses as a matter of routine to keep the nipples covered with a compress saturated with a solution of boric acid. This precaution has had the effect of markedly diminishing the frequency of lymphangitis, but instances of an increase of temperature in young mothers due to microbial infection of the nipples are still numerous. M. Lepage strongly recommends that the nipples should be regularly washed with the following solution: Red iodide of mercury, 10 to 20 centigrammes (2 to 4 grains); spirit of wine, 50 grammes (1½ ounces); glycerin, 500 grammes (1 pint); distilled water, 450 grammes (1 pint). If, after using this for a few days, the ulceration disappears, substitute a solution of boric acid. Any crack that may develop is covered with tarlatan moistened with the mercuric solution. The following figures appear to confirm M. Lepage's good opinion of the comparative value of his method. In three hundred and thirty-one cases of lying-in women whose breasts were treated by the Pinard method there was an increase of temperature in sixty-seven, the corresponding figures in M. Lepage's cases being twenty-three out of four hundred and forty. Moreover, the healing of the cracks is said to be expedited and the pain greatly diminished by the mercurial treatment."—*New York Medical Journal*, March 17, 1894.

#### COMPRESSION OF THE PHRENIC NERVE AS A THERAPEUTIC MEASURE.

The *Journal des Praticiens* for February 10 contains a letter from its Marseilles correspondent, in which its readers are reminded that seven or eight years ago Dr. Bidon conceived the idea of assuaging hysterical spasm of the glottis by exerting digital compression on the phrenic nerve between the heads of the sterno-cleido-mastoid muscle. After that, Leloir advised this procedure as a means of checking hic-cough. Now, M. Bidon suggests it afresh as a remedy for spasm of the glottis in persons suffering with tabes. The following is a summary of a case thus treated: The patient, a man thirty-eight years old, complained of fulminant pains, incontinence of urine, and muscular weakness, and showed Westphall's and Argyll-Robertson symptoms. Every ten minutes he was attacked with vertigo, weakness in the legs, a half-fainting condition, and a sensation of suf-

focation. M. Bidon compressed both phrenic nerves with the fingers. The spasm ceased and the difficulty in breathing disappeared, but only provisionally and for a few minutes after the compression. The use of the measure was persevered in, and in eight days the cure was lasting. "How," asks the correspondent, "is this phenomenon to be interpreted? By a paralyzing action on the diaphragm, or by an inhibitory action on the nervous centres in such manner as to suspend spasm of the constrictor muscles of the glottis, or by direct compression of the laryngeal muscles?" He does not attempt to answer the question, but he remarks that the fact is memorable from a clinical point of view.—*New York Medical Journal*, March 17, 1894.

#### THE DIETETIC TREATMENT OF PHTHISIS.

H. P. LOOMIS, in the *New York Medical Record* for March 24, 1894, in an article upon this subject, says that he is firmly convinced (as are all physicians, for that matter) that diet is a most important element in the prophylaxis of phthisis, and that therefore the regulation of the diet is a most important part of treatment.

Milk should never be taken in quantities exceeding eight ounces at a time, and then should be swallowed slowly during ten or fifteen minutes. When several quarts are drunk in twenty-four hours, lime-water must be added, in the proportion of a tablespoonful to eight ounces. One of the most palatable ways in which milk can be administered is scalded, with Seltzer-water added. This mixture is especially refreshing in the early morning.

Some patients cannot take milk, either from a personal idiosyncrasy or enfeebled digestive powers. To such persons kumyss or matzoon can be given with great benefit.

Where the digestive powers are especially weak, peptonized milk can often be assimilated in large quantities, but the objection to its prolonged use is, that after a time its taste palls upon the appetite. Two to four quarts should be taken in twenty-four hours. The manner of serving it is not unimportant. To some it is more palatable cold, to others hot. In the majority of cases it should be taken slightly warmed (100° F.).

When the different methods indicated all fail, then attention must be given to the gastrointestinal mucous membrane. Potations of hot water (aerated in some cases), from half a pint to a pint one hour before meals, must be tried. If this also fails, disinfection of the alimentary

canal is indicated, and for this creosote is one of the best agents we have.

Meat can be given cooked rare, or, better still, when large quantities are to be taken, in the form of squeezed beef-juice. To obtain from the meat the maximum amount of juice, a meat-squeezer is absolutely essential. There are a number of good ones in the market, which range in price from one to three dollars. The best kind of meat from which to squeeze the juice is a thick round steak free from fat. This should be seasoned with pepper and salt, broiled over a brisk fire, then cut in pieces two inches square, and then put into the meat-squeezer. About eight ounces of juice can be obtained from each pound of meat. No heat can be applied to the juice, as the albumin would be at once coagulated and the juice rendered worse than useless. If the juice becomes cold and it is advisable to heat it, this can be best accomplished by placing the cup in hot water. It is necessary to go fully into the preparation of the beef-juice, because of its importance as one of the most essential items in the diet of phthisis. Freshly-squeezed beef-juice is the best of the artificial preparations of meat known, and the trouble of preparing it is well repaid by the marked improvement in the patient. Beef-tea should never be given in phthisis as an article of diet. The popular idea that it is nourishing is erroneous. Another nutritive and palatable method of preparing meat is in the form of scraped meat-balls. The pulp is scraped from a round steak, either by a fork or by a meat-scraper. This leaves the fibrous material behind. The scraped meat is rolled into small balls and broiled over a quick fire, and served hot with pepper and salt or Worcester-shire sauce.

Scraped meat may also be given raw, spread between thin layers of bread. To some this is a very appetizing method. Many of the meat-powders on the market prepared specially for feeding furnish us valuable aid. A preparation from which the writer has seen marked benefit is the beef peptonoids; also an excellent meat-powder can be prepared in the kitchen by cutting boiled beef into fine pieces, drying by means of a water-bath, and grinding in a coffee-mill with the teeth set closely. [The editor has found beef meat and beef cacao of great value in these cases.] The method of administering these meat-powders can be varied almost indefinitely. The powders can be added to soups, broths, milk-punch, milk, and may be taken in cold or warm water. The object in preparing the meat in the various ways suggested is to give the largest amount

of albuminoids in the smallest compass, in the most palatable form, and in a way that will not disturb the stomach. He has known cases of phthisis to live for months on nothing but milk and meat prepared as above, and gain steadily in flesh and strength.

Next in order to meat and milk as foods come stimulants and cod-liver oil.

It can scarcely be questioned that in consumption alcohol is beneficial. Some attribute to it distinct curative power, and would recommend it in all stages. In the reporter's opinion it is one of those remedies which is capable of doing good, if judiciously used, while at the same time it is quite as liable to do positive harm. It should never be used in the first stage; in the second stage only in small quantities with food, and preferably in the form of milk-punch in the forenoon and on retiring. In the third stage is where it appears to do the most good, when taken in small quantities and repeated at regular intervals. In many cases, in all three stages, a glass of ale or porter twice a day with the meals improves the appetite, aids the assimilation of food, and causes marked increase in weight. For prudential reasons, often it is advisable to disguise the alcohol when given for any length of time. The combination of alcohol with milk, malt, cod-liver oil, or glycerin is theoretically, as practically, more advantageous than its separate ingestion.

It is well known that muscle-fibre is a loose combination of albumin and fat, and that fat is a component factor in all muscular histogenesis. So in phthisis fat is necessary to the building up of health and tissue, and the dietary should be as rich in fat as the assimilative powers of the patient will allow. The greatest evidence of the value of fat in the food of phthisical patients is furnished by the universal confidence placed in cod-liver oil as a curative agent. It is only the best form of fat because it is the most easily assimilated of all, and can frequently be absorbed when no other fat can be. Nature supplies an oil emulsion in milk, and this largely explains its excellent effects. Cream may be used when it is desirable to introduce fat into the system. It has, however, to be given with care, as in many persons it produces dyspeptic symptoms, which may often be obviated by taking it with a little liquor, as maraschino or Chartreuse, or mixed with aerated water, in the proportion of a teaspoonful to a glass.

Albuminoids and carbohydrates should form the basis of the three principal meals. Meat should be eaten rare and with all meals. If the

patient is over thirty years old, a large amount of meat is essential and can be more easily taken. Two pounds of beef, at least, should be eaten in the twenty-four hours, or its equivalent in beef-juice. If poultry is served, the dark meat is preferable to the white. Sweetbreads are often tempting and may assist digestion. Soft-boiled eggs for breakfast are advisable. A raw egg sucked from the shell will often relieve an irritable condition of the pharynx. Butter should be freely used. Cream on cereals, or diluted with Seltzer-water, is of benefit in certain cases.

Milk should constitute the principal drink, and should be ordered between each meal, also a glass or more with the meals. In this way from two to three quarts can be taken in the twenty-four hours. To avoid monotony, the articles of diet, such as vegetables, etc., ordinarily taken with meals, should not be restricted, except that all indigestible articles, as rich pastries and sweets, should be avoided. The starchy and farinaceous foods should be taken sparingly. While the diet is largely nitrogenous, a sufficient proportion of carbohydrates must enter into it. Fats and oils, especially from the animal kingdom, will furnish this. Butter should be freely used.

Cod-liver oil, which is really not a medicine, but a food, should be taken in  $\frac{1}{2}$ -ounce doses after each meal; whether directly after the meal or after a half-hour interval must be decided according to the personal idiosyncrasies of the patient. When it is impossible to give the pure oil on account of its taste, or because it causes indigestion or eructation, it is wise to give an emulsion of cod-liver oil, pepsin, and quinine, which can be readily taken by almost any one. Often the pure oil can be taken when floated on whiskey. During its first stage the phosphates are valuable, and it is advisable to give food which, owing to the presence of phosphates, is desirable. However, it must be remembered that to supply the phosphates in sufficient quantities, special preparations must be made use of. The hypophosphites should be given after meals, diluted in water. In certain cases they are even more valuable than cod-liver oil.

*Second Stage.*—This is the period which will most try the physician's patience, and is the one in which systematic diet is absolutely essential. The relief from coughing, fever, and digestive disturbances experienced by this class of patients in following the dietetic regimen prescribed is of great help to the physician, as a guarantee that his directions will be implicitly followed.

In this stage the diet varies rather in the methods of preparing the food than in the food itself. The patient is still fed six times a day, but the meals are restricted. All foods should be offered in the most palatable form and generally given finely subdivided. This is the stage when beef-juice and scraped beef are specially indicated. A small glass of the former in the middle of the forenoon and afternoon, with a cracker and a scraped meat-ball or raw-meat sandwich for lunch or dinner, will materially aid nutrition. In many cases a glass of porter or ale with lunch or dinner will be of great benefit in increasing appetite and adding flesh.

Milk plain, with lime-water, or boiled should be given early in the morning, at bedtime, and between meals; but this should never be taken at the same time with beef-juice. When milk disagrees with patients, kumyss should be substituted, to the amount of three or four bottles a day. With the exception of the malt liquors with meals, stimulants during this stage are apt to do more harm than good. Cough mixtures should never be taken, if they can possibly be avoided. The syrups and narcotics which they contain are almost certain to produce digestive disturbances, in spite of the most rigid dieting. Cod-liver oil will be required, but the greatest care must be used in its administration. The emulsion spoken of in the first stage will often be assimilated without any trouble. Especially in patients in middle life, the pure oil with whiskey will give the best results. Other cases can take cod-liver oil in capsules.

Some of the most important rules which should govern the dietetic treatment of phthisis may be formulated as follows: 1. Never take cough mixtures if they can possibly be avoided. 2. Food should be taken at least six times in the twenty-four hours; light luncheons between the meals and on retiring. 3. Never eat when suffering from bodily or mental fatigue or nervous excitement. 4. Take a nap or, at least, lie down for twenty minutes before the mid-day and evening meals. 5. The starches and sugars should be avoided, as also all indigestible articles of diet. 6. As far as possible, each meal should consist of articles requiring about the same time to digest. 7. Only eat as much as can be easily and fully digested in the time allowed. 8. As long as possible, systematic exercise should be taken to favor assimilation and excretion; when this is impossible, massage or passive exercise should be undergone. 9. The food must be nicely prepared and daintily served; made inviting in every way. The following may serve as a

sample of a diet-sheet in the early stages of phthisis:

*On Awakening.*—Eight ounces of equal parts of hot milk and Seltzer, taken slowly through half an hour.

*Breakfast.*—Oatmeal or cracked wheat, with a little sugar and an abundance of cream, rare steak or loin-chops with fat, soft-boiled or poached egg, cream toast, half-pint of milk, small cup of coffee.

*Lunch, 10 A.M.*—Half-pint or small teacup of squeezed beef-juice with stale bread; 12 M., rest or sleep.

*Mid-day Meal, 12.30 P.M.*—Fish, broiled or stewed chicken, scraped meat-ball, stale bread and plenty of butter, baked apples and cream, two glasses of milk.

*Lunch, 4 P.M.*—Bottle of koumyss, raw scraped-beef sandwich or goblet of milk; 5.30 P.M., rest or sleep.

*Dinner, 6 P.M.*—Substantial meat or fish soup, rare roast beef or mutton, game, slice stale bread, spinach, cauliflower, fresh vegetables in season (sparingly).

---

*NAPHTHOLATE OF SODIUM (MICROCIDINE) AND TRICHLORACETIC ACID IN EAR- AND NOSE-WORK.*

In the November number of the *Annales de l'Oreille*, COZZOLINO, of Naples, highly commends the product of the action of sodium hydrate upon  $\beta$ -naphthol, as furnishing one of the most valuable antiseptic and curative medicaments for the control of suppurative processes. It is odorless, unaltered by contact with instruments or tissues, soluble in water in the proportion of one to three, forming a brownish solution when strong, but is alkaline in reaction, and nearly colorless and tasteless in the usual three-to four-per-cent. solution. The powder should be kept from the light, but the solutions demand no precautions. Experience in other medical fields has shown the three-per-cent. solution to be as efficacious as 1 to 2000 sublimate solutions, and in the ear Cozzolino has found it twice as prompt in ending suppuration as boric solutions, using it by irrigation to secure full washing away of all discharge. In the nose he employs it in .5- to two-per-cent. solution or in a weak ointment, and claims brilliant results for it here, as well as in tonsillar troubles.

In another article, Cozzolino warmly commends trichloroacetic acid as the best hæmodynamic in epistaxis arising, as such bleedings usually do, from the cartilaginous septum. He employs generally a pledget of cotton soaked

with one-per-cent. or 1.5-per-cent. solution, and claims slight reaction and prompt cicatrization as the result, far surpassing that following chromic acid or iron preparations.

---

*TREATMENT OF CONJUNCTIVITIS.*

SCHWEINITZ (*Philadelphia Polyclinic*, April 7, 1894) thinks that in the treatment of acute and subacute simple conjunctivitis the following points should receive attention:

1. Removal of the probable cause.
  2. Protection of the eyes with dark glasses or a shade, but *never the application of a poultice.*
  3. Exposure of the surfaces which are inflamed by eversion of the lids and bringing into prominence the retrotarsal folds, and spraying the affected areas with a mild antiseptic solution, preferably boric acid and common table salt.
  4. The application of nitrate of silver in the usual manner once a day, if there is much secretion. If there is not much secretion or swelling, and the inflammation becomes subacute and tends to be stubborn, the use of an astringent, such as alum, or tannin and glycerin, and of a collyrium of biborate of sodium, instead of boric acid.
  5. The frequent washing of the lids and surrounding areas with warm water and Castile soap.
  6. The administration of the internal medication which is indicated, particularly quinine, which has a good effect in checking the disease.
- Associated inflammation in the naso-pharynx or surrounding facial area—as, for example, eczema, impetigo, and similar conditions—necessarily requires attention and treatment, and the relation of refractive anomalies to the disease should always be determined.

---

*THE TREATMENT OF BLEPHARITIS MARGINALIS BY HYDROGEN DIOXIDE.*

S. C. AYRES (*Medical News*) strongly recommends the use of hydrogen dioxide in the treatment of blepharitis. The method of application is as follows:

The larger crusts should first be removed or scraped off, after having been softened by tepid water. Then a little cotton is wrapped tightly around a Japanese toothpick, which is dipped into the dioxide in a little dish. The cotton is then swept over the entire edge of the lid. The characteristic bubbling will follow, and the application is repeated until the bubbling ceases. The ulcers will then present a whitish

appearance. If care is taken, and the cotton is not too freely saturated, none will come in contact with the conjunctiva. In order to obviate all pain, a few drops of a four-per-cent. solution of cocaine can first be instilled into the eye. This treatment should be repeated every day. The remedy is one that any intelligent person can apply at home, and one from which there is no danger. Dr. Ayres's experience with the use of salves and ointments is somewhat disappointing. They often cause unaccountable irritation, and on this account are unreliable. In the method advised a clean remedy is used, which acts promptly and efficiently. By its chemic action it destroys the germs which cling so closely to the edges of the lids. It is not a cure-all or a specific, but he certainly has had the happiest results from its use.

*THE VALUE OF HOMATROPINE AND  
COCAINE DISKS AS SUBSTITUTES  
FOR ATROPINE, DUBOISINE,  
AND HYOSCINE.*

CASEY WOOD (*Ophthalmic Record*, March, 1894), as the result of additional experiments, reaches the following conclusions, some of which are modifications of the propositions contained in his first research on this subject:

1. If two gelatin disks, containing  $\frac{1}{10}$  grain each of homatropine and cocaine, be placed in the conjunctival sac at an interval of twenty minutes, *the eye being all the while kept closed*, the ciliary muscle will in most instances be found to be fully paralyzed in from seventy to one hundred minutes after the introduction of the first disk.

2. In persons under twenty-five years of age, or whenever ciliary spasm is suspected, the best results are obtained by the use in another twenty minutes of a third disk, or one containing  $\frac{1}{10}$  grain of homatropine alone, the examination in that case being best made between ninety and one hundred and twenty minutes after using the disk. The first two disks containing cocaine are sufficient to furnish the chief advantage which, in his opinion, resides in that alkaloid,—namely, of increasing the absorbing powers of the cornea for agents combined with it, while the increased dose of homatropine produces a more thorough relaxation of the ciliary muscles.

An eserine disk ( $\frac{1}{1000}$  grain) inserted the following morning will enable the patient to do near work within an hour or two.

3. The disks should be inserted on the tip of a damp camel's-hair brush, and should al-

ways be applied to the ocular conjunctiva at its inferior and outer surface, the patient looking up and in, while the lower lid is drawn down. Any adherent or sticky gelatin may be easily wiped off the palpebral edges with a damp cloth or a piece of wet absorbent cotton.

*PRACTICAL POINTS IN TREATING DIS-  
EASES OF THE EYE, EAR, NOSE,  
AND THROAT.*

J. WALTER PARK (*Journal of the American Medical Association*, April 7, 1894) calls attention to the importance of attending to the nasal lesions in phlyctenular keratitis, believing that if the eyes alone are treated and the nose is neglected, there will be persistent relapse.

He entertains a most favorable view of the removal of the ossicles and tympanic membrane for chronic suppuration of the middle ear, believing that when there are no mastoid complications, eight out of every ten cases of from six months' to three years' standing, that have resisted all other forms of treatment, recover if the operation is properly performed. In all acute and chronic suppurating ears pyoktanin is recommended, as it will often arrest the discharge quicker than boric acid, if it is always used in fresh solutions, not over three to five days old. Park employs it in 1 to 500 strength, and believes it has a more lasting effect in the destruction of pus-germs than peroxide of hydrogen.

In the treatment of nasal troubles he recommends fluid petroleum, combined with various antiseptics, as an excellent medicament to prevent crust-formations, believing that the fluid petroleum is better adapted for the mucous membrane of the nose than albolene or benzoïnol.

*THE TYMPANIC COMPLICATIONS OF  
CHILDREN'S DISEASES.*

A valuable communication is made by RASCH, of Copenhagen, in *Hospitals-Tidende*, Nos. 18 and 20, 1893, of the results of sixty-one autopsies of children under two years of age. In but five cases was the tympanum normal, suppurative disease being present on one or both sides in forty-six, equalling seventy-five per cent., and catarrhal lesions in eight cases, or fourteen per cent. Nearly all of the children who had died of broncho-pneumonia showed otitis, and in thirty-three of the forty-three in which the secretion was rigidly examined the pneumococcus was present. Not a few of these children had shown symptoms leading to a diagnosis of meningitis, which was found absent on sec-

tion, and the tympanic inflammation had been generally overlooked. Perforation of the drum-head was found but four times, and even when this occurs, the condition is too frequently unrecognized or slighted.

This is only a confirmation of what has been long urged and repeatedly demonstrated by otologists, but they too often are merely regarded as magnifying their office unreasonably. Numbers of such cases recover from the general disorder without recognition of the middle-ear disease, and give no evidence for a time that resolution has not been complete there; but the otologist finds a really normal drum-head a rarity, and must frequently trace later-coming deafness to such beginnings. This is the more deplorable when measures as simple as hot douching of the ear will often suffice to cure the disease in its early controllable stage; and a careful use of the Politzer inflation has at times instantly dispelled the symptoms of meningeal involvement, which delay might have made organic and irremediable.

#### TRICHLORACETIC ACID AS AN IDEAL CAUTERANT.

The January, 1894, *Monatsschrift für Ohrenheilkunde* contains an enthusiastic paper by Von Stein, of Moscow, in furtherance of his primary claims for this medicament. Some of the advantages urged can hardly be claimed for anything else, and the methods seem to deserve full trial. Admitting that it is more painful than chromic acid and less vigorous than galvanocautery, he differentiates the non-fibrous hypertrophies as the true field for its use as a cauterant; but claims, as the result of clinical and laboratory experience, to have demonstrated that it is an adjuvant of the greatest value to the other forms of cauterization, increasing the efficiency and lessening the reaction. The application of the crystals or concentrated solution to a bare or eschared surface prevents all putrefactive changes, almost wholly does away with febrile consequences, and promotes rapid, comfortable healing. Further, his employment of it in ozæna cases has not only speedily controlled the odor, reduced crust-formation, and hastened improvement, but has even led to so decided a hypertrophic tendency of the sclerosing surfaces as to demand at times reduction by decided cauterization. In acute coryza he has employed weak solutions (1 to 1000 to 2000) by instillation or spray, with prompt and safe resolution after the brief increase of secretion, and otitic consequences have seemed especially rare in cases thus antiseptically treated.

He cautions against strong applications until the tolerance and inadequacy of weaker solutions have been proved; and others will do well to be more conservative than he now is, since he sometimes insufflates crystals into the Highmore or ethmoid sinuses. While the conditions which he selects for its use as a cauterant seem those in which still milder measures would succeed, and his view is generally rather roseate, trichloracetic acid would seem to have a special place as an aid in other cauterizations, and may prove our most valuable medicament in combating the obstinate ozænatous conditions.

#### INTUBATION OF THE AUDITORY CANAL FOR STENOSIS AND FURUNCLE.

In the *Annales de l'Oreille*, etc., for December, DR. COURTADE reports some very satisfactory results in the treatment of inflammatory stenosis of the meatus by the elastic pressure of a short piece of rubber tubing, and claims exceptional value for the method. The idea of elastic pressure is undoubtedly good, and his means of applying it often the best possible. Pressure has been the reviewer's main dependence for the promptest possible relief of the pain and its exciting inflammation, although it may seem rather paradoxical to fight pressure-pain by pressure; yet the relief is rarely slow of attainment, extension is lessened, if not prevented, and the unknown and perhaps serious condition in the depths of the canal is promptly made accessible to study and treatment. Only when the stenosis is accompanied by a deeper suppuration, which may not be safely clogged by a tampon in the canal, does a tubular compress offer a radical advantage, for the conical wedge of cotton, well covered with the yellow-oxide ointment, serves to gently and persistently afford the desired compression and rub in the medicament with every motion of the parts, as in each movement of the jaws. The germ theorists will find no better germicide for the purposes of disinfection than this affords, while it is admirably stimulant and resolvent.

In the majority of the cases of stenosis other than furuncular, there has been, and often still persists, a suppuration of the tympanum, and sealing of the meatus may then be precarious. Tubes have then their great advantage, though not exactly for Courtade's reason, that cleansing cannot be adequately done by more ordinary methods. One who knows how to properly syringe the auditory canal (it is a pity and a shame that so few do) need have little difficulty in fairly douching the whole canal. A small speculum gently used as a dilator will

overcome almost any inflammatory swelling which does not demand operation, and the syringe can be used with full effect. To maintain the dilatation a tube may be well employed, and the soft elasticity of caoutchouc may surpass a quill or other rigid tube. Dr. Courtade makes no mention of the device—sometimes very valuable—of stretching the tube in introducing it, so as momentarily to reduce its volume; then its expanding tendency is far more powerful, as it needs to be when the stenosis is annular, firm, and fibrous. This may be accomplished by passing long, delicate forceps through the tube to grasp the farther end, and exercising firm traction upon the nearer end until the other is well beyond the stricture. The hour-glass form of the compressed tube serves then the additional valuable purpose of anchoring it securely at the desired place until the reduction of the swelling sets it free. Too hasty removal of the tube or compress may easily permit relapse.

#### TREATMENT OF CANCER OF THE STOMACH.

PRIEUR (*La Tribune Médicale*, No. 12, 1894) holds that three drugs are particularly efficacious in the treatment of cancer of the stomach,—condurango, sodium chlorate, and aristol.

Condurango has been known since 1871 as a remedy in the treatment of cancer. Friedreich reported a surprisingly rapid action. Rees, later, out of fifty cases, could not fairly attribute any beneficial effects to the drug, excepting in three cases. This medicine may be administered in the form of the wine, a tablespoonful five or six times a day shortly before meals, or the tincture may be employed, a teaspoonful three times a day. Although this drug has no specific action, its influence upon the appetite and upon the digestion is sufficiently marked to justify its use in the treatment of cancer.

Chlorate of sodium has recently been recommended by Brassaud. He gave it in doses of from 2 to 4 drachms, and, as a result, noted cessation of hemorrhage, increase in weight, diminution in swelling, cure of vomiting, and return of appetite. One patient gained twenty-five pounds in six weeks. Albuminuria must be considered a contraindication to the use of this drug. Aristol, in doses of 1 to 2½ grains daily, is used simply as an antiseptic.

The symptomatic treatment of cancer is also of great importance. Alimentation should receive first consideration. A vegetarian diet which minimizes the work of the stomach

sometimes serves an excellent purpose. As a rule, meat is not borne by these patients. White meat of fowl, fish, and soft-boiled eggs can, however, often be taken. Milk is nearly always well borne. When this begins to fail, koumyss should be substituted. Nourishment administered three times a day is sufficient. Frequent administration of small quantities simply increases suffering.

Since the stomach contains no hydrochloric acid, this should be administered by the mouth half an hour after meals as a digestive, and as an antiseptic when the stomach is empty,—that is, in the morning on rising and in the evening on retiring. Bicarbonate of sodium may be given, but always in small doses and before meals, since, thus administered, it increases the secretion of gastric juice. If given after meals in full doses it diminishes the secretion. When ulceration takes place, the administration of hydrochloric acid must be dropped and pepsin and pancreatin given. To combat the anorexia, condurango should be tried first, this failing, simple bitters are indicated. Thus, the following formula may be given:

R Nux vomica, ℥ss;  
Chloroform, ℥ss;  
Tincture of gentian, q. s. ad ℥iii.  
Sig.—℥i three to six times daily before meals.

Or chloroform may be given in 20- or 30-drop doses. It should be administered half an hour before meals.

Vomiting, when it is reflex and irritative, as in the beginning of the affection, is treated by cocaine or morphine. These drugs are given according to the following formula:

R Morphine hydrochlorate, gr. iv;  
Cherry-laurel water, ℥iv. M.  
Sig.—5 drops is required.

Or,

R Morphine hydrochlorate,  
Cocaine hydrochlorate, of each, gr. iv;  
Cherry-laurel water, ℥iv.  
Sig.—5 drops is required before meals.

If the vomiting comes from dilatation of the stomach or atony, full doses of strychnine should be administered. When from imperfect digestion, meat should be dropped from the diet and hydrochloric acid and pepsin given. When vomiting comes from obstruction, lavage of the stomach represents the best treatment. Properly carried out, it gives great relief to symptoms and prevents dilatation. Often following the washing out of the stomach the patients will gain from ten to twenty pounds. One- to two-per-cent. solution of chlorate of sodium, one-half-of-one-per-cent. solution of

salicylic acid, or two-per-cent. boric-acid solution may be employed. Contraindications to lavage are hæmatemesis, gastrorrhagia and acute inflammatory symptoms, and profoundly-marked cachexia.

When alimentation is rendered absolutely impossible, nutrient enemata should be administered. The lower bowel should first be emptied by a large injection. All injections administered should be digested or at least contain digesting materials. Thus, if milk is employed, the water and salts alone are absorbed. Experimentally it has been determined that if two dogs are starved and one is given copious injections of broth or soup and the other nothing, they will both perish at about the same time.

Schmitt advises defibrinated blood one-quarter of a pint at a time. Flint orders a little over a pint of a mixture made up of finely-chopped beef, 300 parts; fresh pancreas, 50 parts; and water, 200 parts. A quarter of this is given each time.

As to surgical intervention, Billroth, who has a record of twenty-eight pylorectomies, records two cases of survival, one four and a half years after operation, the other two and a half years after.

The author states that, even if the surgeon successfully removes a cancer, and this is not followed by recurrence, the atrophy of the mucous membrane which always accompanies this growth progresses, the absence of the hydrochloric acid persists, and the patient dies of degenerative lesions of the stomach.

#### TREATMENT OF CHRONIC URETHRITIS.

LYDSTON (*Journal of Cutaneous and Genito-Urinary Diseases*, No. 139, vol. xii.) holds that by far the greater proportion of cases of gleet require anterior internal urethrotomy. When the patient objects to the operation he should be informed that all other measures are in the nature of a compromise.

When the inflammation is localized in the bulbo-membranous portions of the urethra, topical applications are necessary. He prefers a syringe holding half an ounce and the ordinary Ultzman instrument, using, of course, solutions of nitrate of silver of comparatively feeble strength.

The passage of a steel sound is to be commended, but copious antiseptic injections represent by far the best method of treatment of both anterior and posterior inflammation. The strength is varied according to the individual tolerance. In order of merit he places perman-

ganate of potassium, nitrate of silver, and bichloride of mercury. The permanganate is used in the strength of 1 to 5000 to 1 to 15,000; nitrate of silver from one-half to one per cent. These irrigations are made by means of a short urethral nozzle. Rheumatic, gouty, and syphilitic diatheses must always receive appropriate general treatment. Certain cases are practically incurable. Sometimes absolute cessation of treatment is the best possible procedure that can be advised.

#### TREATMENT OF GONORRHOEA IN WOMEN.

LUTHER (*Sammlung Klinischer Vorträge*, Nos. 82 and 83), after a careful review as to the etiology, symptomatology, and pathology of gonorrhoea in women, proposes the following prophylactic measures:

Regulation of prostitution; legislation by which all professional harlots should be required to live in buildings provided for the purpose. A change in the method of examining women. Compulsory examination of all men coming to a brothel; enforced punishment of all who, knowing they are suffering from venereal disease, expose another person to contagion without a certificate of health from a reputable doctor. The right of summoning physicians to testify as to sexual infection, excepting when this takes place in the marital state. Requiring the monthly nurse, in virtue of her authority, to report all venereal diseases of which she becomes cognizant, except when they occur in the persons of married women. The organization of a corps trained in methods of scientific examination, and especially in instruction of the monthly nurse as to diagnostic signs; release of the medical commissioner from the performance of the duties of a doctor.

These highly practical methods of prevention would scarcely be proposed from other than a German source.

#### CASE OF EPILEPTIFORM TRIGEMINAL NEURALGIA TREATED BY HORSLEY'S OPERATION FOR NEURECTOMY OF THE INFERIOR DIVISION OF THE FIFTH NERVE.

MAYO ROBSON (*British Medical Journal*, No. 1716) reports the case of a publican of the age of sixty, who suffered for fifteen years from severe agonizing paroxysms of pain shooting down the right side of his face in the course of the inferior dental nerve. The paroxysms

only lasted about half a minute, but recurred generally about every half-hour or at longer or shorter periods, and were brought on by eating or at times even by talking. He had his teeth removed on the advice of his doctor, and took various medicines at the hands of several medical men, without any real relief. Seven years ago Mr. Robson divided the inferior dental nerve from the inside of the mouth, which operation completely relieved him for two years. The attacks then recurred after exposure to cold, and soon became as severe as before. He was readmitted into the infirmary, when the lower jaw was trephined by Robson opposite the last molar tooth, and half an inch of the right inferior dental nerve removed, giving complete relief for four years, or until eight months ago, when the attacks returned after exposure to cold and damp.

He was readmitted January 26, 1892, suffering from severe paroxysms of pain in the right side of the face, not only shooting down in the course of the inferior dental nerve, but radiating all over the right half of the face. They lasted about twenty seconds, occurred on an average every quarter of an hour, and were brought on by eating and talking.

In the early part of February another operation was performed. Incision was made a little above the upper border of the zygoma, extending forward for about an inch and a half, another downward from this behind the ascending ramus of the jaw, and another from the angle of the jaw along the lower border for about an inch. The flap thus marked out was reflected with the subjacent fat; the branches of the seventh nerve and the parotid duct were exposed, and the interval between them defined. The fascia was then divided, the gland pushed aside, and the masseter muscle exposed. The fibres of the masseter were divided transversely, so far as they were in the way, and retracted. The periosteum was then raised from the subjacent bone, the sigmoid notch and its boundaries well defined, and all bleeding stopped. A  $\frac{1}{2}$ -inch trephine was used, and a piece of bone taken out of the jaw just below the notch, so as to deepen it; a second piece was then removed, and then a third, and on it was found the groove for the entrance of the inferior dental nerve. On sponging out the cavity and getting the wound as dry as possible, the nerve could be seen lying at the bottom.

An attempt was made to ligature the internal maxillary artery, but, on account of its great depth, this was found impracticable, hence pressure-forceps were applied and left

on. It was not necessary to divide any extensive portion of the internal pterygoid muscle. The nerve was grasped with a pair of pressure-forceps and drawn downward, when a piece three-eighths of an inch in length was removed from just beyond the foramen ovale. The wound was well washed out with hot lotion (1 to 4000 perchloride of mercury solution), stitched up with silkworm-gut above and below, and left open in the middle for the forceps. Stitches were inserted into the middle of the incision, but were left untied until the clips could be removed. The wound was dressed with cyanide gauze and antiseptic wool. The pressure-forceps were removed the next day, when the loose sutures were drawn up and knotted. The stitches were removed on the tenth day, and the patient returned home on the twenty-seventh day quite well, having had no return of pain since the operation, the parts supplied by the inferior division of the fifth nerve being devoid of sensation.

#### *A CASE OF ENTERECTOMY FOR GAN- GRENOUS BOWEL.*

The following case is reported by PAUL (*British Medical Journal*, No. 1727, 1894) to refute the objection urged against his operation, that it would not always be possible to invaginate the enlarged proximal end of the bowel into the distal shrunken end, and in such cases would therefore be useless. He believes it unimportant which way the bowel is invaginated, though the downward method should probably be preferred when feasible.

S. R., aged fifty-one, came under his care at the Royal Infirmary on June 20, 1893. She was a rather delicate-looking woman; had never been very strong since she suffered from spinal curvature as a child of eleven. Early in December, 1892, a week after lifting a heavy weight, she first noticed a lump in the left groin; it was soft and painless, and had remained there ever since. For a few months she had been subject to attacks of vomiting near the menstrual period, unaccompanied by any change or pain in the lump. One of these attacks commenced very suddenly on June 14 and continued two days. On June 17 medical treatment was instituted with success until June 19, when vomiting returned and was inclined to become stercoraceous. There had been no movement of the bowels nor passage of flatus since June 14.

On June 20 patient was seen by the writer for the first time; the abdomen was slightly distended; there was severe umbilical pain, abso-

lute constipation, and vomiting, together with a small femoral hernia, tense but painless. Her general condition was quiet, pulse under 90, temperature 98.2° F. She was at once taken to the operating-theatre and anæsthetized. The sac was opened, exposing a small portion of bowel, which looked recoverable, but upon releasing the constriction and drawing down a little more bowel, the contents began to ooze through an ash-gray slough on the proximal side. The bowel constriction extended an inch and a half; on the distal side there was no distinct slough. Incision was made in the median line between the umbilicus and the pubis, a sponge introduced beneath the inner opening of the hernial sac, the bowel cleansed in the sac, reduced with the left hand outside, and rapidly withdrawn from the abdomen with the right hand, previously placed inside to receive it. The peritoneum remained clean during the process. The bowel was then clamped above and below, the injured part quickly cut out with the scissors, the bleeding-points tied, and one of Paul's bone tubes (made of decalcified bone. For detailed description of Paul's method, see *Lancet*, May 30, 1891), one inch by one and a quarter inches, sutured into the upper end. The upper end was dilated and thickened, and it proved impossible to invaginate it into the shrunken lower end. The tube was, therefore, changed for a smaller one (five-eighths of an inch by one and a quarter inches), which was sutured into the lower end. The traction thread was passed, the cut ends attached, and invagination performed. The bowel was invaginated upward instead of downward, a variation which was not found to increase the danger in the original experiments on dogs. As the traction thread had been passed through distended and, perhaps, partially paralyzed bowel, the needle puncture was secured with a single Lembert suture. Fine green catgut was used for all internal sutures, and fishing-gut for the abdominal wall. The abdomen was closed without drainage, after sponging out of the peritoneal cavity a little blood-stained serum which was present before the operation. The hernial wound was closed above, the lower part being left open for drainage. The entire operation, including anæsthetization, lasted one and a half hours. Patient promptly recovered from slight shock of operation. Vomited a little during the night and complained of pain in the back. She progressed favorably until the eighth day after operation, when she had an attack of pain and sickness, apparently due to excess of food, from

which she promptly recovered on lessening the amount given. The highest temperature reached was 99.2° F. on the evening of the sick attack. Six weeks after operation she left the hospital cured. Half a year later had had no return of trouble and pursued her avocation of nursing.

In the same number of the *British Medical Journal*, HORROCKS cites a case in which excision of intestine for malignant disease and circular enterorrhaphy by Paul's method was successfully performed. The case is as follows:

C. H., a married woman, aged thirty-eight, was admitted to the Bradford Infirmary on August 29, 1893, with obstruction of the bowels. She had been an in-patient in October, 1892, with similar symptoms, which were relieved by starvation and opium. She suffered almost constantly from severe abdominal pain, shooting round the loins to the back. The pain was spasmodic, sometimes lasting several hours, and when very severe caused emesis. The bowels were usually relaxed, but during and after the severe attacks of pain they were confined, sometimes for several days. She had had four children; menstruation was painless and regular. She showed no signs of general wasting, though of spare habit. A systolic bruit was heard at the apex, which was not displaced. The abdomen was somewhat full at the lower part, with the umbilicus everted and the skin marked with atrophic scars. The percussion-note was normal over the abdomen. Above Poupart's ligament on the right a solid tumor was felt; it consisted of two parts, divided by a vertical groove.

By vaginal examination the uterus was found displaced downward, with cervix pointing towards the sacrum. Occupying the right fornix and extending in front of the uterus was a rounded swelling, which was continuous with the tumor felt above the pubes. This mass felt hard. It was divided into two parts by a groove and moved independently of the uterus.

On September 29 an exploratory abdominal operation was performed, in which the tumor was found to implicate a considerable portion of the small intestine; the wound was closed and healed without complication. On October 19 the writer operated, the operation lasting an hour and twenty minutes, with chloroform anæsthesia for the first twenty minutes and ether for the remainder of the time. An incision three inches in length was made in the median line rather above the umbilicus. The tumor was adherent to the abdominal wall, along the line of the old scar, which was below the fresh incision. The adhesions were mainly broken down, but the most adherent

part of the abdominal wall was cut away with the growth. The tumor was then drawn out of the abdomen and the opening packed with antiseptic cloths. The intestine beyond the growth on each side was emptied, and an elastic tube was passed through the mesentery around the gut. A V-shaped piece of mesentery, containing enlarged glands, was separated and the bleeding vessels tied. The bowel was now cut across transversely on each side of the growths and the implicated intestine with its attached mesentery removed. A Paul's bone tube was inserted into the open end of the intestine of smaller lumen and the free margin of the bowel stitched to the end of the tube with continuous silk suture; the thread was passed through the holes in the tube and the muscular and peritoneal coats of the intestine. Additional stitches were inserted at the mesenteric attachment. The other cut end of the bowel was now brought into apposition, after the threaded needle connected with the tube had been passed through the intestinal wall from within out, about three inches from the incised extremity. The two ends of the bowel were now stitched together by a continuous Lambert silk suture. By traction on the thread and manipulation of the bone tube the bowel was invaginated for about three-quarters of an inch. It was fixed in this position by a continuous silk suture, which included only the peritoneal and muscular coats. The needle was now cut from the traction thread, which was drawn into the gut. The margins of the mesentery were stitched, partly by interrupted, partly by continuous sutures. The extremity of the vermiform appendix was inflamed and adherent to the tumor. The appendix was ligatured near its proximal end, the distal end removed, and the stump closed in by three silk sutures. The abdomen was cleansed and a glass drainage-tube inserted, with its lower end reaching the bottom of Douglas's pouch. The abdominal wound was closed with silkworm sutures, the end of the drain projecting at the lower end of the wound.

The intestine removed was about thirty-nine inches long. At two places its wall was invaded by growth; the growth was about the size of an orange, consisting of tumor and convoluted intestine, fixed by firm adhesions. The lumen of the intestine was much narrowed and the mucous membrane ulcerated at this point. There was a second growth of smaller size, separated from this by healthy intestine. The mesentery showed several enlarged and infected glands. The growth was a large round-celled sarcoma rising from the submucous tissue.

The patient quickly rallied from the operation, and was discharged November 23, 1893.

#### PRESCRIPTIONS.

*Carbolic Acid in Pruritus.*—The following preparation is spoken of highly :

R Acid. carbolicæ, ℥iss;  
Liq. potassæ, ℥i;  
Ol. lini, ℥i;  
Ol. bergamot, ℥iii. M.  
Shake well before using.

*Simple Remedy for Coryza.*—*Revue Médicale* gives the following as an excellent remedy for coryza: A ripe lemon is taken and some of its juice squeezed into the palm of the hand. The juice is then forcibly inhaled up the nostrils. Two or three such inhalations will suffice to cure an ordinary cold.

*Nitro-Glycerin in Sciatica.*—DR. LAWRENCE (*Revista de Ciencias Medicas de Barcelona*) reports the case of a carpenter, aged fifty-two, who suffered for several weeks with sciatica. In order to alleviate the pain he had become a morphine user and could not abandon the habit. After trying a multitude of drugs, he gave him a 1 to 100 solution of nitro-glycerin, 1 drop three times a day, gradually increasing the dose to 5 drops. Relief was almost immediate, and in ten days he could resume his work, completely cured.

*Epistaxis.*—Plethoric cases are relieved by :

R Tinct. aconit., gtt. viii;  
Liq. ammon. acetat., ℥i. M.  
Sig.—Teaspoonful every half-hour.

In anæmic cases may be employed :

R Strychniæ sulphat., gr. ½;  
Tr. ferri chlor., ℥ii;  
Vini ergotæ, ℥ss;  
Syr. simplices, ℥iss;  
Aq. destill., q. s. ad ℥vi. M.  
Sig.—Teaspoonful three times a day.

—*Medical Press and Circular*, January, 1894.

#### HYSTERECTOMY BY THE PRATT METHOD.

LANPHEAR (*Journal of the American Medical Association*, vol. xxii. No. 4) performed the above operation in a case of uterine tumor in which laparotomy disclosed a uterus so enlarged and fixed in the pelvis that it was impossible to remove it by abdominal hysterectomy. The patient was anesthetized; the perineum and the peritoneal body slit through to give room; the uterine arteries temporarily tied by the method advocated by Dr. F. H. Martin. The tying

of the arteries is an innovation of Lanphear's, Dr. Pratt claiming it to be unnecessary. The uterine canal was packed tightly with gauze, then cut with a knife entirely around the cervix through the mucous membrane and the sub-mucous tissue, until the free and loose connective tissue which envelops the body of the uterus was reached. The fingers were then introduced within the slit and rapidly tore away the uterus and its tumor from the peri-uterine structures. This was rapidly accomplished. Caution should be exercised in approaching the fundus, lest the peritoneum which covers the uterus at this point be penetrated. Very little hemorrhage occurred. For the removal of the uterus and tumor not more than ten minutes were required. The whole operation, including sewing up of the perineum and packing the cavity with iodoform gauze, can be accomplished within twenty-five minutes.

This operation will probably prove an admirable one for cases of this kind, and it is possible that it is also applicable in cases of early epithelioma of the cervix.

#### *SURGICAL TREATMENT OF VARICOCELE.*

SEBILEAU (*Gaz. de Médecine de Paris*, February 24, 1894), after giving the ordinarily accepted indications for operation in case of varicocele, holds that the same method of treatment is not suitable for all cases. When the varicocele is small, the dilated veins being of normal consistence and regularly distended, simple resection of the scrotum is followed by the best results, although in combination with this there should also be resection of the lower segment of the posterior group of veins. When, however, the enlarged veins are greatly enlarged and extend the whole length of the cord, when these veins are partially dilated, indurated, and knotted, a double operation is necessary,—that is, not only is it essential to resect the scrotum and excise the posterior funicular group, but the anterior group must also be operated upon. As palliative means in the non-operative cases, cold douches are recommended to the region of the scrotum and perineum. For these douches, one-per-cent. tannin solution is advised; wearing a suspensory, careful attention to the condition of the bowels are also insisted upon as cardinal points. Resection of the scrotum is a safe operation, the author holds. The parts are prepared as for ordinary surgical intervention. The redundant tissue is pinched up, seized in a clamp, and cut off. Only enough to cover the testicle is left. After resection the clamp should

be removed, hemorrhage checked, and the wound sewed. The wound is not drained. After having checked immediate bleeding, an examination should be made of the veins lying behind the vas deferens. These are readily seen and separated through the large wound incident to the resection of the scrotum; each should be separately seized, tied above and below, and the segment between the ligatures cut out. When the varices have reached their largest development, after resection of the scrotum and excision of the posterior group the wound is sewed as before. An incision is then made along the course of the cord from the external inguinal ring. The various layers of cellular tissue are dissected off, exposing the anterior group of veins surrounded by a little fat. In excising this group the deferens canal and the spermatic artery must be avoided. The artery lies behind the anterior group of veins, and behind it, in turn, lies the deferent canal, together with the deferential artery; and finally, behind these structures is situated the posterior funicular group of veins with the arteries of the cord. It is sometimes difficult to avoid the spermatic artery, since it is so small that its pulsation cannot be detected and is completely concealed by the large veins. Perhaps the best way of avoiding seizing this artery is not to include the whole anterior branch of veins in the thread.

#### *CAMPBOR NAPHTHOL IN THE TREATMENT OF TUBERCULAR ADENITIS.*

RABOUL (quoted in *Centralblatt für Chirurgie*, No. 11, 1894) warmly commends camphor naphthol in the treatment of tubercular adenitis. In some reported cases the favorable results were most striking; in others abscess and fistula followed. It is claimed in favor of this method that there is no danger of intoxication and the treatment is practically painless. It must, however, be long continued. It is interesting to note that Ménard and Calot have reported cases of intoxication following injection of camphor naphthol in abscess cavities. The patient suffered from frequent rapid pulse, loss of consciousness, and epileptiform attacks. The quantity of the drug injected was about 6 drachms. This patient recovered. In another case, eight years of age, 1½ ounces of the solution were injected. In the third case, aged twelve, 5 drachms. In these last two cases life was saved by freely opening the cavity and washing it out on the first appearance of toxic symptoms.

## Reviews.

OUTLINES OF OBSTETRICS. By Charles Jewitt, A.M., M.D. Edited by H. F. Jewitt.  
Philadelphia: W. B. Saunders, 1894.

This work is a syllabus of the lectures delivered at the Long Island College Hospital, and if one can judge of the teaching of the institution from such a syllabus, the instruction in obstetrics in Brooklyn must be very good. Indeed, the publication of Dr. Davis's somewhat larger book at the Jefferson College, which we have reviewed elsewhere, that of Dr. Norris's, which is a syllabus of Professor Hirst's lectures at the University of Pennsylvania, and this one of Professor Jewitt's may be taken as types of the best teaching of this subject to be found anywhere. Jewitt's book is not in the style of the quiz compend, nor is it as full and complete as that of Dr. Davis's. It is not in the form of questions and answers, as are many of the works issued by this publisher, but may be considered as a very condensed epitome. We notice that directions are given for the hypodermic injection of half a drachm of the fluid extract of ergot to prevent post-partum hemorrhage, but nothing is said about the particular method of employment which should be resorted to to prevent unnecessary irritation following such a means of treatment, and we can see no reason why the earlier administration of the drug by the mouth would not in the majority of cases be equally serviceable.

HOW TO USE THE FORCEPS, WITH AN INTRODUCTORY ACCOUNT OF THE FEMALE PELVIS AND OF THE MECHANISM OF DELIVERY. By Henry G. Landis, A.M., M.D. Revised and enlarged by C. H. Bushong, M.D. Illustrated.

New York: E. B. Treat, 1894.

This book by the late Dr. Landis, whose career in the medical profession was so full of promise, has been brought up to modern ideas by Dr. Bushong, and presents in more detail than can be found in the ordinary work on obstetrics the subject of which he treats. We cannot, however, see that there is any reason for the average practitioner purchasing a separate monograph on this subject unless he intends to devote himself entirely to obstetrical work. To such the book can be cordially recommended.

A MANUAL OF PRACTICAL OBSTETRICS. By Edward P. Davis, A.M., M.D. Second edition, revised and enlarged. Illustrated.

Philadelphia: P. Blakiston, Son & Co., 1894.

There have been few books of this size published in this country or abroad which have

been received with such universal favor by reviewers as has this one, which possesses the advantage that its author has not made a condensation from standard works, but has written of obstetrics as only a practical obstetrician of large experience can write. A number of original full-page illustrations are found through the work, and the advice which is given on disputed points in treatment is at once sufficiently progressive to show that the author is in touch with the latest improvements in his art, and yet is governed by the conservatism so necessary to the practitioner of this branch of medicine. We predict for the second edition of Dr. Davis's work an even greater success than that which was obtained by the first.

CLINICAL DIAGNOSIS. By Albert Abrams, M.D. Third edition, revised and enlarged. Illustrated.  
New York: E. B. Treat, 1894.

We regret that the publishers of this work have placed upon the market such a poor example of American book-making, so far as the printing and illustrations are concerned. Many of the pages are not only crooked, but badly blurred or so imperfectly printed as to render reading difficult. The book consists to some extent of abstracts from articles published elsewhere by Dr. Abrams, and is a curious mixture of physical diagnosis, practice of medicine, and therapeutics. The fact that it has reached its third edition proves that it must have been popular with some practitioners, and naturally there is much in its pages which is of value. On the other hand, there are books of the same size and cost which are certainly better.

LECTURES ON GENITO-URINARY DISEASES. By J. C. Ogilvie Will, M.D., C.M., F.R.S.E. With numerous illustrations.

London: The Scientific Press, Limited, 1894.

The five lectures published in this book are by no means intended to cover the entire subject of genito-urinary diseases, but rather to express the author's beliefs and experience gained from the study of certain selected cases.

The first lecture deals with urethral fever. Will holds that catheter fever is due to putrefactive germs which gain access to the bladder by regurgitation of air through the instrument. In this belief he probably stands alone. As the surest way of avoiding urethral fever, the application of cocaine to the urethra and the general employment of steel instruments are advised. Quinine is a drug in which much reliance is placed. A watery solution of sodium bicarbonate is referred to as a reliable antiseptic for washing catheters.

In the second lecture on the treatment of retention of urine, Syme's dictum that there is

no such thing as an impermeable stricture is supported. Continuous dilatation is advocated. As the best way of tying in a catheter, it is suggested that a small ordinary elastic band should be placed in the groove behind the corona glandis; two waxed silk threads are secured to the end of the catheter and passed under this band.

In the treatment of gleet kaolin is recommended. By mixing this with water or oil a thick paste is made. With this paste the urethra is filled by means of a common syringe. A bit of lint is placed over the meatus and retained there as a cork. This injection is allowed to remain in the urethra until the next urinary act, after which the process is repeated. The result is that friction of the inflamed surfaces is absolutely prevented, healing takes place, and the discharge ceases.

In the treatment of varicocele the open method with excision is preferred. Hydrocele should be treated by injections of iodine, this method failing only in exceptional cases.

The final lecture is devoted to the treatment of syphilis. Excision of a chancre is not commended. Mercury is administered before the manifestation of secondaries, and should be given continuously for six months and thereafter intermittently for two and a half years.

There is an appendix containing formulæ used in the treatment of syphilis.

This work, though not entirely modern in its teachings, represents the honest convictions of one who has evidently had large experience. It provides interesting and instructive reading to the general practitioner, and in the main mirrors the methods and beliefs of the present day.

BURDETT'S HOSPITAL AND CHARITIES ANNUAL, 1894.

Edited by Henry C. Burdett.

London: The Scientific Press, Limited, 428 Strand,  
London, W. C., England.

This book is best described in its title-page as containing "a review of the position and requirements, and chapters on the cost of management, of the voluntary charities, and an exhaustive record of hospital work for the year. It will also be found to be the most useful and reliable guide to British, American, and colonial hospitals and asylums, medical schools and colleges, religious and benevolent institutions, dispensaries, nursing and convalescent institutions."

As will be seen from this abstract, it covers a very large amount of information, and to those interested in hospital management it will prove an invaluable guide.

## Correspondence.

LONDON.

(From our Special Correspondent.)

*Consultations at St. Bartholomew's Hospital.*  
—My last visit to St. Bartholomew's Hospital happened to be on a Thursday afternoon, and, having finished the particular business on which I had come, I strolled in the direction of the operating-theatre, where I found one of the weekly "consultations" in full swing. To the already qualified man, or to the student shortly to take his qualification, I think there is no part of the hospital training likely to be of greater value, for here are presented all cases in which there is a difficulty in diagnosis, besides a great many which exhibit rare or unusual conditions. To show how highly these consultations are esteemed in the hospital itself, I need only add that every member of the staff who can do so makes a point of being present, and that the theatre is full from top to bottom of those eager to hear the opinions of their more experienced teachers.

The *modus operandi* is as follows: The patient whose case is to be discussed is brought in, and the notes of his case, including the history of the malady, so far as it can be ascertained, are read out by the surgeon, who draws special attention to the salient features and makes a statement as to its probable nature. All remarks, however, which might give pain or anxiety to the patient are carefully avoided. After this each member of the staff makes an independent examination of the patient, who is then taken back to his ward. The surgeon in charge of the case then states the diagnosis at which he has arrived and the treatment he is inclined to adopt, or, in cases of great difficulty, he states the various constructions which may, in his opinion, be put on the case and the reasons therefor. The other surgeons, in order of their seniority, then give their views as to diagnosis and treatment. Needless to say, there is often great divergence on both points, but no view is expressed without a full statement as to the reason for holding it.

The casual visitor may think that the mere hearing of opinions upon a case with regard to which he has had no opportunity of forming his own conclusions is of doubtful utility to him. If this view should strike him, I would only desire to point out that the "consultation cases" are an indication of the most interesting patients in the hospital, and that all the visitor has to do, if he takes a particular interest in any of the cases shown, is to afterwards visit the wards

with the surgeon, when he will have ample opportunity of making any personal examination which he may care for. Personally, I know of no portion of the post-graduate training which is of greater value to the young practitioner who will take the trouble to thus follow up a case, and in this manner acquire practice in differential diagnosis.

*The Gynaecological Theatre at St. Bartholomew's.*—In former letters I have given brief sketches of our Casualty Department and also of the department devoted to the treatment of cases by electricity. I have described, I hope impartially, the advantages and disadvantages of our out-patient system, and have done my best to give such indications of what goes on as to induce visitors to come and form their own conclusions. I now wish to make a few remarks on our arrangements for operative gynaecology, a subject which has of late years attracted an enormous amount of attention. And at the outset I would say that it is by no means held that the arrangements are the best which could possibly be devised; they are, however, probably as good as one can obtain without the erection of entirely new buildings. The present operating-theatre was built a good many years ago, at a time when the paramount importance of the strictest asepticity was not understood as it is now. Not so long ago it was held that any room would do for the performance of such an operation as that of abdominal section, provided a sufficient quantity of antiseptics, etc., were poured into and around the wound before and during the operation. Now it is the great object of every operator not to saturate his patient with antiseptics, which may of themselves both fail to kill microbes, and may so lower the resistance of the parts to which they are applied as to render them an easy prey to the bacteria which escape destruction. It is now sought to insure the perfect asepticity both of the room, the patient before operation, and of everybody and thing which may come in contact with her; and it is the more or less perfect realization of this idea which has, no doubt, contributed to the greatly increased measure of success attending abdominal operations of late years, although increased experience has, of course, also played an important part in bringing about the same end.

To return to my subject. "Martha" theatre was constructed when antiseptic surgery was the fashion. It has, therefore, many, but not all, of the advantages of the most modern operating-room. The floor is laid in closely-fitted, narrow teak boards; the walls are painted, so as to allow of frequent and care-

ful cleansing, but they would have been decidedly better had they been, partly at least, tiled. The wash-basin is fitted with hot- and cold-water taps, and the waste is carefully trapped, the trap being fully exposed, so as to allow of the prompt detection of leakage. To avoid all possibility of sewer contamination, the waste-pipe discharges into the open air as quickly as possible. The theatre, which is about nineteen feet square, is lighted both by large side windows and by skylights. It is warmed by hot-water pipes and by a fireplace on the south side.

All the fittings of the room, even to the operating-table, are made, so far as possible, of glass and metal. The top of the operating-table is fitted, besides, with a large copper tray to contain hot water (130° F.), an important adjunct in the prevention of shock in cases of long exposure. The glass above this is covered by a clean sterile blanket, on which the patient is laid. There are two other tables of similar construction, to hold respectively the dressings and instruments. The furniture of the theatre is completed by a large glass irrigator, slung from the ceiling and capable of holding three gallons of sterilized water; an air-tight instrument cupboard, with glass shelves and metal pegs for holding instruments; and three sterilizers,—a small, shallow, oblong one for boiling instruments, a large barrel-shaped one, holding nine gallons, for preparing sterilized water, and an oval dry sterilizer for sterilizing dressings. This last is fitted with a perforated false bottom to prevent the dressings from becoming scorched from coming into direct contact with the possibly overheated copper bottom. All other instruments are, it is needless to add, so made as to be capable of thorough cleansing and sterilization. On the evening before an operation the theatre is specially prepared. The windows and ventilators are opened and left open all night, the floor is carefully polished, and the walls, basins, and all other things washed with sublimate. Sterilized water is prepared, and dressings are placed in the sterilizer, heated for twenty minutes to 356° F., and left there until required. All these precautions are adopted because it is the conviction of the operator that the time when septic conditions are introduced is that during which the abdominal wound is open, and that once this is closed the septicity or asepticity of the operation is practically determined. Precautions are completed, so far as the theatre is concerned, by again going over everything on the morning of the operation with a cloth damp with sublimate.

Such is our operating-theatre and the pre-

cautions to insure asepticity. The results obtained lately have been in every way most encouraging. I hope, however, to return to these matters on a future occasion.

#### "CEREBRINE" AGAIN.

To the Editors of the THERAPEUTIC GAZETTE:

DEAR SIRs:—I have made a chemical examination of the "cerebrine" so called of Dr. William A. Hammond, to the single end of determining the presence or absence of nitro-glycerin. I have made this examination (1) of the article furnished in the market as Dr. Hammond's "cerebrine," and (2) of the preparation made by me, according to Dr. Hammond's published directions, in process of completion.

1. The article of "cerebrine" of the market I obtained for analysis directly from Hege-man & Co., 196 Broadway, New York, on September 15, 1893, and on September 25, 1893. The article as I received it was contained in bottles holding five to six centimetres when full, and labelled "Sterilized Solution of Cerebrine. Dose, 5 minims dropped on the tongue or hypodermically. Prepared by Columbia Chemical Company, 90 South Fifth Avenue, New York." Diagonally across the face of the label is the red script "William A. Hammond." The contents of eight of these bottles were used in the chemical examination. I find that this article—the "cerebrine" obtained from the market as above—contains nitro-glycerin. I reach this conclusion from the concurring evidence of the several chemical reactions of nitro-glycerin. Some of these reactions are clearly given by the cerebrine liquid just as it is taken from the bottle, and all of the reactions of nitro-glycerin are obtained after due procedure for its separation. When so separated the concentrated product gives the characteristic reactions of nitro-glycerin with vivid intensity; and I find that the concentrated product agrees with nitro-glycerin in its physiological effect, as a poison. The procedure for separation of nitro-glycerin from the "cerebrine" is fully effectual, so that the remaining cerebrine liquid offers a negative response to all the qualitative tests for nitro-glycerin.

2. The preparation of "cerebrine," by the directions published by Dr. Hammond, I placed in maceration on October 14, 1893. I have macerated the brain of the ox and the contained blood in a mixture of equal parts of absolute alcohol, glycerin, and a saturated solution of boric acid in water, with frequent

agitation and strong pressure, five months and twenty days, and have then made chemical examination of a portion of the product. The product, at this period of maceration, perfectly agrees in appearance every way with the "cerebrine" which I obtained from Messrs. Hege-man & Co. last September. But the "cerebrine" of my preparation, under the directions published by Dr. Hammond, with the time of maceration just stated, does not contain a trace of nitro-glycerin. It fails to give the slightest reaction for ethereal nitrates of any sort, and the procedure for separation of nitro-glycerin in concentration yields nothing but negative results when subjected to all tests for this body.

Yours, very truly,

ALBERT B. PRESCOTT,

*Professor of Organic Chemistry in the University of Michigan.*

## Notes and Queries.

---

### AMERICAN MEDICAL ASSOCIATION.

The Committee of Arrangements has worked indefatigably on the matter of transportation rates, trying to get a round trip for a single fare.

By advice of Mr. T. H. Goodman, General Passenger Agent of the Southern Pacific Company, who furnished addresses, we sent out circulars to agents of all roads interested in the matter.

About one-half of those replying favored our petition, and promised to advocate it before their respective associations, through which all such matters must be arranged.

The following communications from Mr. Goodman place the matter, as it now stands, in a clear light:

"SAN FRANCISCO, March 16, 1894.

"DR. R. H. PLUMMER,

*"Chairman Com. of Arrangements, A. M. A.,  
652 Mission Street, San Francisco.*

"DEAR SIR,—This morning's mail brings us your yesterday's letter, handing for our perusal three letters from Eastern railway officials. Having read the letters you sent, we return them herein, and beg to emphasize our previous statements to you in person and by letter, that the Trans-Continental roads have virtually done what you ask,—namely, accorded a one-way rate.

"In other words, the rate for a thirty-day ticket from Missouri River points to San Francisco is \$60.00. Excursion—that is, round-trip—tickets, Missouri River points to San Francisco and return, are being sold to-day at

a rate of \$65.50. Such tickets require the going trip to be made within fifteen days from date of sale, and the return trip within fifteen days after the day upon which the ticket is signed here in presence of a railroad agent, but in no event later than July 15 next.

"We have told you that within the State of California we ignore this fifteen-day limit on both going and returning trips; in other words, that the holders of the tickets are at liberty to move at will within the State of California within the life of the ticket, and that the fifteen-day limit returning is not enforced west of our terminals at Portland, Ogden, and El Paso.

"You have asked our permission to state positively that these Midwinter-Fair rates would be in force at the time attendants at your convention will want to move westward. We have replied that the traffic is west-bound traffic, and that we do not control the matter. You will doubtless, however, recollect our telling you that this rate would, in all probability, hold until after that period. We gave you our reason for that statement,—namely, that one of the roads had announced that it would continue the sales up to June 30.

"We appreciate your desire for an authoritative statement in this regard. As we cannot make it, we write you that we feel you are quite safe in stating the fact that such rates have been announced, and that the sale would continue until that date.

"We beg to again call your attention to one point, which is quite material in this matter. The Trans-Continental roads having virtually done what you asked, you should bring all the influence to bear that you can upon the roads east of the Trans-Continental roads. Those roads are, for the most part, the ones forming the Western Passenger Association, the Central Traffic Association, and the Trunk Line Association. The Western Passenger Association roads lie between the Missouri River and Chicago and St. Louis. You should go to them for a rate similar to our Midwinter-Fair rate. They tell you their rate will be \$20.00, Chicago to Missouri River and back, and \$12.00, St. Louis to Missouri River and back. As the single-trip rate, Chicago to Missouri River, is \$12.50, and from St. Louis \$7.50, you will see that their rates are not reduced nearly so much as the Trans-Continental road rates. Can you not through some of your profession at Chicago approach the general passenger agents of the lines leading from Chicago whose names we have given you? We think they will appreciate the importance of the occasion.

"One of our assistants has in hand the matter

of reduced rates locally, and you will be shortly advised.

Respectfully yours,

"T. H. GOODMAN."

Extracts from letter of February 12, 1894:

"The rates thus continued are as follows: \$65.50 from Missouri River points, being Sioux City, Council Bluffs, Omaha, Pacific Junction, St. Joseph, Atchison, Leavenworth, and Kansas City; \$77.50 from St. Louis, Cairo, Memphis, and New Orleans.

"The rates mentioned to you exceed the one-way thirty-day rates as follows:

"That from the Missouri River by \$5.50, that from St. Louis, Cairo, Memphis, and New Orleans by \$10.00, and that from Chicago (\$85.50) by \$13.00.

"We deem it but proper to here mention that if our Shasta route between San Francisco and Portland is passed over on either going or returning trip from Missouri River, St. Louis, or Chicago, the rate will be \$15.00 greater.

"As on this occasion passenger movement is from the east to the west, it is but proper that the question of rates should be taken up with officials of Eastern roads. We suggest, therefore, that you correspond first with those who have charge of the passenger traffic of the so-called Trans-Continental Association roads. They are as follows:

\* \* \* \* \*

"For rates from the territory lying beyond the Missouri and Mississippi Rivers you should address: Mr. B. D. Caldwell, Chairman Western Passenger Association, Chicago; Mr. F. C. Donald, Commissioner Passenger Department Central Traffic Association, Chicago; Mr. L. P. Farmer, Commissioner Passenger Department Trunk Line Association, New York; Mr. M. Slaughter, Assistant Commissioner Southern Passenger Association, Atlanta, Ga."

\* \* \* \* \*

From the foregoing communications it will appear that, while we have not been wholly successful, if the roads between the Missouri River and Chicago and between Chicago and Atlantic points, where local travel far exceeds that over the Rocky Mountains, will give the same reductions as the roads from the Missouri River points to San Francisco, we will practically have a single fare for a round trip.

Cannot the profession in the East by united efforts secure these concessions?

The time is growing short, and chairmen of the different sections should send in their reports, etc., for insertion in the programme.

### A NEW BLOODLESS OPERATION FOR THE EXCISION OF HEMORRHOIDS, WITH HEALING BY FIRST INTENTION.

BY H. M. BISHOP, M.D., LOS ANGELES, CAL.

IN the domain of surgery no field has been fought over more energetically in modern times than that which pertains to operations on the rectum, and particularly to the removal of that most important, because so common and distressing, ailment, hemorrhoids. The

most valorous determination to rescue its treatment from the uncertainties and vagaries of empiricism and to establish it on sound surgical principles has actuated the advocates of the various methods now in vogue.

Believing that a process of dealing with hemorrhoids, evolved from my own conceptions after many years of contemplation and trial in devising means to harmlessly control hemorrhage while excising the tumors and redundant folds of the rectum, and likewise to hold in perfect and undisturbed coaptation the edges of the incision, will receive favorable consideration from intelligent and unbiassed promoters of advanced surgery, I will, without further

consumption of valuable time, enter *in medias res* with as little vexing of the polemics of the subject as possible.

The following is the *modus operandi*: With a lateral or dorsal decubitus, as convenience or expediency may decide, and with an aseptic perineum and dilated sphincter, gently and smoothly clamp the base of the hemorrhoids with suitable forceps, so as to parallel the approximated surfaces and free them from folds and other inequalities; then, having left room between the clamp and adjacent healthy tissues, apply on either side a sufficient length of rubber tubing five or six millimetres in diameter, with a lumen of one millimetre, and secure with aseptic catgut after the general manner of the quilted suture. To assure accuracy of adjustment, the pieces of tubing should be of the same length, and have corresponding marks six or eight millimetres apart, indicating the locations for the sutures. Each tube should have its extremities hermetically sealed by the sutures there tied, thus adding a degree of pneumatic elasticity to that possessed by the rubber. All the sutures should be preapplied or tied beforehand to one of the pieces of tubing, with threaded needles in each of the opposite loops, ready for transfixing the tissues and tying over the other piece of tubing. Remove the forceps, and excise the tumor close to the rubber tubing with flat scissors. I have sometimes varied the fixation of the tubing by using one piece doubled upon itself and drawn together with a continuous suture, made to assume an advancing figure of eight, or double spiral, by passing the needle always close to the forceps and the thread always encircling the tube from below upward; the perforations then are in one line and the tension evenly distributed. Where many stitches are to be taken, it saves the time consumed in tying. This completes a bloodless operation, for the elasticity of this welted suture supplies sufficient pressure to prevent all hemorrhage, and maintains in perfect and uniform contact the margins of the wound without endangering from local asphyxic and necrotic conditions consequent to rigid clamping and without interfering with the plastic exudation of repair by first intention.

The further dressing of the wound consists simply in passing a strip of moist borated gauze into the rectum, leaving an end protruding from the anus. The catgut sutures soften in due time and permit the tubing to pass away, while the flexibility of the latter has adapted itself to the environments, with the minimum of annoyance to the patient.

What the Esmarch bandage is to amputations, the same is this elastic quilted suture to the removal of hemorrhoids or other angiomas from surfaces sufficiently lax to allow of approximating folds of sound tissue at their base. Compared with the ligature, it possesses all its advantages with none of the disadvantages attendant upon the distorted, puckered strangulation of the parts, followed by sloughing and ulcerative healing. The clamp and cautery also leave surfaces of crushed and lacerated tissue which the hot iron at best must transform into a burn of the second grade, with inevitable cicatricial contraction. Whitehead's operation is prolix, tedious, and wasteful of the vital fluid. The injection of carbolic acid is unreliable and precarious, save in expert hands, and even then we must wait for nature to expel the mummified mass and fill in with granulation before the cure is perfect. The accidents and lack of success that have been known to attend these various methods are apologetically attributed by their champions to unskilful hands. I feel confident that this new method will succeed with those who make no claim to extraordinary cleverness. It approaches the ideal of operative exæresis, and attains the desiderata of all surgery,—speedy and clean removal of the condemned part, economy of blood, and primary union.

436 BRADBURY BUILDING.

#### FRACTURES OF THE NECK OF THE FEMUR AND THEIR TREATMENT.

BY BEDFORD BROWN, M.D., ALEXANDRIA, VA.

MY personal experience in fractures of the neck of the femur comprises fourteen cases. Of these, about ten per cent. died in less than twelve months from complications, as inflammation and suppuration at the seat of injury, and fever; two per cent. were bedridden for the balance of life; the remainder recovered sufficiently to walk with the aid of a cane or crutch for the balance of life. All the bedridden cases were of the extracapsular variety, while the cases that recovered the power of locomotion were of the intracapsular non-impacted variety.

All of these cases of fracture of the neck of the femur occurred in females varying in age from sixty to eighty-five years. These fourteen subjects presented every variety of conformation of figure. In two there was great obesity. In some the figure was tall and spare, while in others it was quite *petite* and very delicate

and slight. In one the figure was that of a very robust woman a little over sixty. In one, a woman of eighty-five, the weight did not exceed eighty pounds and the person was very emaciated.

*Causes of Fracture of the Cervix Femoris.*—The causes of this fracture may be classified as the direct or major and the indirect or minor.

The major form of cause is always from direct violence, as a sudden fall from a distance on the hip, or a violent blow or great pressure from mechanical causes on the same point. On the contrary, the minor causes are always of the indirect variety from unusual sudden pressure on the foot while walking, a slight misstep, sudden twist of the foot in walking.

A knowledge of the major and minor or direct and indirect character of the existing causes will aid us materially in differentiating the variety and location of the fracture. The major or direct causes almost invariably cause the extracapsular variety of fracture with or without impaction, while the minor or indirect causes produce intracapsular fracture.

*Symptoms.*—In all cases of suspected fracture of the neck of the femur, the entire person, from the anterior superior spinous process of the ilium to the toes, with exception of the external genital organs, which can be protected from view by a napkin, should be exposed to inspection. After the clothing has been removed above the pelvis, we are at once enabled to see the relationship of the two opposite trochanters to each other, their corresponding appearance, their relative prominence. We can also observe the relative positions of the two limbs throughout their entire length, and we can better detect the slightest eversion of the foot, the least departure in its direction, and at the same time the least degree of shortening of the limb. Much of the information gained by this investigation is in these cases derived from comparative observation. The trochanter should first be examined. In the fractured bone, except in cases of impaction and non-displacement of the fractured ends, the trochanter is depressed and flattened, compared with the sound side, and when moved from side to side the arc of the motion is considerably reduced. Extending our investigation downward, we observe the lower or tibial end of the patella does not correspond with that on the sound side. It is from a quarter of an inch to an inch above the line of that of the sound limb. Continuing our observations to the foot, we find a shortening of the limb to the extent of from a quarter of an inch to an inch and a quarter in length; at the

same time we find the foot of the injured limb everted. When by our own aid we correct this eversion, it invariably returns spontaneously, and when the patient is requested to correct it she is unable to comply with the request. Here we have a typical picture of a simple fracture of the cervix femoris: first the depressed flattened trochanter, the difference in the line of the corresponding patellæ, the shortening of the limb and eversion of the foot. When the entire person is exposed, without any movements of the patient or manipulation on our part, the eye can detect these peculiarities at a glance.

Then, again, in non-impacted fracture, if an assistant grasps the foot of the injured limb, and alternately extends and relaxes the limb, while the attendant grasps the trochanter and presses it firmly towards the pelvis, distinct crepitus may be detected.

*Methods of Differentiation between Intracapsular and Extracapsular Fractures.*—In determining the important question whether a fracture is intra- or extracapsular, is non-uniting or uniting, the peculiar character of the cause assumes diagnostic importance. It may be said, with much degree of certainty, that shortening of the limb to the extent of a half or one inch, eversion of the foot, moderate pain in the hip, no indications externally of contusion, some crepitus on extension, flattening of the trochanter occurring after a slight indirect injury, as a very sudden misstep, striking the foot against the floor or steps forcibly, or a sudden twist or wrench of the foot from any slight cause in the aged, denote intracapsular fracture, with no possible tendency to unite. On the contrary, shortening of the limb to the extent of from one to two inches, with eversion of the foot, great pain in the hip, flattening of the trochanter, effusion in the surrounding tissues in front and rear of trochanter, crepitus on extension in the comparatively young, much contusion of soft parts from a major form of cause, as a violent fall, blow, or pressure directly on the trochanter, denote extracapsular fracture, with tendency to union of ligament.

Then, again, a slight shortening of the limb and eversion of the foot, with much pain on attempted motion, absence of crepitus, slight ability to raise the limb or stand upon the foot, great effusion in front and rear of trochanter from a violent direct injury to the trochanter, with contusion of soft parts, indicate impacted fracture.

*Diagnosis of Impacted Fracture of the Cervix Femoris.*—The two cases of impacted fracture of the neck of the femur which came under my

observation both resulted from indirect and violent causes. In one the patient was seventy years old, and had a violent fall directly on the trochanter of that side. The trochanter was found, on comparison with the opposite side, to be flattened and depressed, and very tender on pressure. There was considerable swelling back of the trochanter, and in front, below Poupart's ligament, there was great swelling and much pain and tenderness. There was entire loss of power over the limb and inability to stand on it.

Shortening of the limb was imperceptible and eversion was entirely absent. The injury occurred more than six years since, and the patient has never recovered the use of the limb and is still comparatively bedridden.

The second case occurred in a comparatively young person, with symptoms identical to those of the former, and has never recovered a fair degree of locomotion in the limb since the injury.

*Complications.*—One of the most serious complications observed in my experience has been symptomatic fever following the injury. It is more apt to occur in the extra- than the intracapsular variety, because the causes are of a more violent character and the anatomical structures of the part are more extensively lacerated.

I never saw but one case of protracted fever following intracapsular fracture in an aged person recover, and that was in the case of a woman aged eighty-five. She recovered, and lived in comparative health and comfort to reach ninety years, and then died from hemiplegia.

A temperature ranging from  $101^{\circ}$  to  $103^{\circ}$  F., a quick pulse, pain and restlessness, denote serious organic changes going on in the injured structures, that if permitted to progress will continue until extensive inflammation, effusion of exudates, and suppuration intervene.

*Treatment of Fractures of the Neck of the Femur.*—There is no class of fracture that requires the exercise of more judgment in their treatment or more accuracy in diagnosis than fractures of this kind.

In one variety of fracture—the extracapsular—in those below middle life we can with safety adopt means to bring about union. To adopt the same means in intracapsular fracture in the aged would insure certain death; hence the importance of an accurate differential diagnosis.

*Treatment of Intracapsular Fractures.*—In my own experience a good rule to work by in treating intracapsular fractures of the cervix

femoris in the aged is not to expect union of the fractured bones, but, on the contrary, to so conduct the management of the case as will, if possible, insure a good, strong false joint, by which, after a time, the patient can regain a fair degree of locomotion for the balance of life. To bring about this desirable object, the pelvis from the anterior superior spinous process is enveloped with a broad flannel roller four inches wide and fifteen feet long, applied down below the trochanters. This flannel bandage gives comfort by the support that it affords the fractured bones and the prevention of too much motion, and gives opportunity to the soft parts involved to throw out adhesive exudations. This is the full extent of the apparatus to be applied. As for the balance of treatment, pillows long and short, small and large, are to be relied on for splints and supports. Comfort of position is to be the guiding rule in the management of this class of cases. The ingenuity of surgeon and nurse will be taxed to so arrange the pillow-splints as to insure comfort, relieve pain, and secure sleep. When these objects are accomplished all has been accomplished that judgment and experience can do until inflammatory action subsides and the process of fibrinous exudation is completed, and then the false joint is ready for use. To attempt, on the contrary, to confine this class of patients in a stiff apparatus, with the view of accomplishing that which no power can ever effect,—a union of bone or ligament,—is to condemn our patient not only to unnecessary suffering, but to certain death.

In the treatment of extracapsular fracture from violent and direct causes in the comparatively young, we may calculate with a degree of certainty on ligamentous union, provided the method adopted will maintain perfect adaptation of the fragments, and we can adopt such method and apparatus as will insure this end without fear of detriment to the patient's health. After the pelvis has been firmly enveloped in the broad flannel roller, as in the former case, then Buck's extension apparatus is applied and the extension maintained until union takes place, which is usually about six weeks.

In impacted fracture my method of treatment has been to envelop and support the pelvis and fractured hip-bones by means of the flannel bandage, which I consider better and more comfortable than a simple band. For the purpose of supporting the limb and preventing motion, which might cause dislocation of the fractured bones, two sand-bags are used, the longer external reaching from above the pelvis below the foot, the other, shorter,

reaching from a little below the external genitals on the inside of the limb below the foot. These arrangements appear to meet the desired ends better, in my own experience, than any other.

*THE INJECTION IN PNEUMONIA AND  
TYPHOID FEVER OF SERUM  
FROM CONVALESCENTS.*

READ BEFORE THE SECTION IN PATHOLOGY OF THE PAN-AMERICAN MEDICAL CONGRESS.

BY W. E. HUGHES, M.D., PH.D.,  
Visiting Physician to the Philadelphia Hospital; Physician  
to the Out-Patient Department of the Children's  
Hospital; Instructor in Physical  
Diagnosis in the University  
of Pennsylvania,  
AND

W. S. CARTER, M.D.,  
Assistant Demonstrator of Pathology in the University of Pennsylvania;  
Pathologist to the Children's Hospital.

BEFORE taking up the consideration of the actual cases of these injections themselves, let us glance briefly at the conditions which have led up to them, the evolution of theories which have made them possible, and the final results, towards which they are but stepping-stones. And these are all bound up within the problem of immunity,—a problem which has ever engaged the attention of observers, a problem which has baffled even theory, and the solution of which will go far towards the rounding out of the circle of medical investigation.

Immunity is natural or acquired. Natural immunity is first, inherent in races or species, due here either to processes acting along the lines of evolution or, on the other hand, to the continued failure of the causative microbe to adapt itself to conditions existing in the host; second, sporadic,—that is, existing in scattered individuals of a species,—a condition difficult of explanation, but probably, again, evolutionary. Acquired immunity, differing radically from the natural, is brought about by a slow habituation to the poison, probably by a process analogous to vaccination, by vaccination itself, or else is due to a previous attack of disease. It is this acquired immunity which is so difficult of explanation,—a difficulty shown by the numerous theories brought forward towards its elucidation, and by the warmth of support which every one of these theories has elicited.

The theories which at present are most prominent, and, indeed, to which all others may in some manner or other be referred, are that in which the cells play an all-important rôle (phagocytosis), and that which attributes the whole protective power to the blood-serum. The old explanation given for immunity before

the part played by bacteria in the production of disease was clearly known—that of exhaustion of the soil—has been almost completely cast aside; unfortunately so, perhaps; for, reasoning by analogy with the higher vegetable growths, it is more than possible that this may eventually demonstrate itself to be a most important factor. However, it is not our purpose here to discuss at length the theories of immunity, much less to attempt to decide between them; the ground has been so thoroughly gone over that to reharrow it would be wearisome as well as useless, and, too, the time is not yet ripe; there are as yet too few facts in our possession; our knowledge does not yet extend far enough to make a definite decision tenable.

There are, though, some facts necessary to be made prominent, lest we fall into error. While bacteria are the cause of a disease, yet its symptoms are due not to the bacteria themselves, but to products attendant upon their growth, and the destruction of these products, while causing an abatement of the symptoms, may still have no effect upon the bacteria and may not be at all concerned in the production of immunity. Again, care should be taken not to identify the action of blood-serum with that of blood-plasma, for it is well known that while serum may be strongly bactericidal, yet in the plasma from which the serum was drawn the bacteria may flourish luxuriantly. Further, as the *ultima Thule* of our investigations is the preservation of life, we must not be led away by theories looking to brilliant immediate results, but rather gather together our facts slowly and surely, looking not for an instant reward, but hoping everything at the hands of the future.

The knowledge that we have acquired of the production of immunity is briefly this. The introduction into the blood of animals of immune blood, of attenuated bacteria, or of the products of bacterial growth may render these animals unsusceptible afterwards to that disease. Whether this immunity is due to a failure of the bacteria to grow or to a loss of lethal power of their products is a moot point; at least this much is evident: it is the result of some change in the condition of the immune animals. Most experiments have been done upon animals; the few on human beings are much the most valuable, but at the same time much more liable to error and to lead to false deductions. It can readily be seen why this must be so. We cannot control nearly so completely the conditions which surround a man as those among which a white rat lives.

The first impulse is to attempt to produce a cure, to brilliantly imitate nature or even to

improve on her, and, stepping in suddenly, end a disease. But it must be steadily borne in mind that the production of a cure is not necessarily the production of immunity; cure and immunity may not be strictly synonymous. It is true that after the cure immunity follows; but may not the production of cure be merely a step in the production of immunity? May it not be brought about in various ways, and the destruction of the symptom-producing toxins a process so varied and indefinite that even after its nature is fairly understood it may be of little practical importance? Therefore it would seem possible that, while the destruction of the toxins may seem the simplest and easiest way of attaining our end, yet in reality that end can be attained only through a thorough understanding of the deeper processes that underlie the production of immunity and be protection rather than cure. The only disease in which such protection has been a perfect success is small-pox, and here vaccination was stumbled upon, and its processes are even yet not understood. The only other disease in which efforts have been made to produce results by a process similar to vaccination is hydrophobia, and here the success is somewhat doubtful. On the other hand, in three diseases—tetanus, measles, and pneumonia—a cure has been striven for by the injection of immune serum. Because a certain result follows a certain procedure in one disease is no good reason why this should hold good in an allied disease. We know too little of the life histories of micro-organisms to generalize successfully. That there are different methods for the production of immunity, and so different methods of cure, is probable from the existence of natural immunity. The blood of animals naturally immune seems to have little effect in conferring immunity, nor does the serum from such blood differ in its bactericidal power from serum from susceptible animals. In the three diseases above mentioned the procedure adopted has been the injection of serum from animals or persons rendered immune by previous vaccination or disease. Here, looking at the results obtained, the theory has been advanced that the cure is brought about by a neutralization of the toxins, and that it is this antitoxic material which confers immunity. In tetanus, the method has been a success; in measles, at least doubtful. Pneumonia, which more nearly concerns us at present, was experimented upon first by the Messrs. Klemperer. They announced the following facts: Animals can be immunized by the introduction into their blood of the sterilized products of the diplococcus; heating these

products to 140° F. hastens the process. This immunity is conferred only after the lapse of some time, and is attended by fever. The introduction of immune serum confers immunity immediately. This paper was soon followed by the publication of other cases. Among others, we published\* a case where we used intravenously defibrinated blood, and gave our reasons against a repetition of such a procedure. Since the publication of our paper, Audeoud† and others have placed cases on record, till at the present time there are records of thirty-nine cases, of which all but one have been successful.

The fourteen cases of the present series, which we shall ask you to consider, were selected carefully, as being typical, and taken at a time when there would be little danger of confounding the result obtained from the injection with the natural crisis. In all serum was used, which was obtained most frequently by venesection, occasionally by blistering. The serum was injected subcutaneously, this having been found to be as efficacious and less dangerous and troublesome than intravenously.

CASE I.—In Philadelphia Hospital. Man, (negro) aged twenty-six years; pneumonia involving whole of right lung; general symptoms of quite marked severity; temperature averaging about 103° F.; diplococci in sputum. On the fourth day of the disease, at 2 A.M., 7 cubic centimetres of serum were injected, and again at 9 P.M. 25 cubic centimetres. The first injection was followed by no change whatever in the temperature. Twelve hours after the second it fell to 101° F., but rose again immediately, though never to the height it had maintained before the injections. It was not till the eighth day that the crisis occurred and the temperature fell to normal. After this there was a secondary rise, the normal being finally maintained after the tenth day. Beyond the trifling lowering of the temperature after the injections, there was no effect produced upon the general symptoms. Resolution of the affected lung was rather slow than otherwise.

CASE II.—In Philadelphia Hospital. Man, aged fifty years; alcoholic pneumonia of moderate severity; consolidation involving part of lower left lobe; temperature not high, ranging between 101° and 102° F.; diplococci in sputum. On the fourth day 25 cubic centimetres of serum injected, which was followed in twelve hours by a subsidence of the temperature to normal and a complete amelioration of the

\* THERAPEUTIC GAZETTE, October 15, 1892.

† *Rev. Méd. de la Suisse Romande*, February 20, 1893.

general symptoms. The man died, however, about a week later of uræmia. The death could in no wise be attributed directly to the pneumonia, convalescence from which was complete. Albumin and casts had been noted in the urine during the febrile period, and it is probable from his history that the Bright's disease antedated by some time the pneumonia.

CASE III.—In Presbyterian Hospital. Man, aged sixty-seven years; both lungs involved irregularly at the bases, but consolidation nowhere perfect; general symptoms of great severity; typhoid state; low, muttering delirium; marked heart-weakness. Temperature quite irregular, ranging between  $100^{\circ}$  and  $104^{\circ}$  F. Diplococci present in abundance in the sputum. On the ninth day, at 4 P.M., 25 cubic centimetres of serum injected. On the next day, at 1.30 P.M., 15 cubic centimetres. The injections had absolutely no effect upon either the temperature or general condition, and the man died six hours after the administration of the second one. The post-mortem examination showed a condition of lungs suggestive rather of broncho than of lobar pneumonia, although there were present copious virulent diplococci.

CASE IV.—In Presbyterian Hospital. Man, aged forty years; right apical pneumonia; symptoms of moderate severity, temperature averaging about  $102^{\circ}$  F.; diplococci in sputum. On the fourth day, at 4 P.M., 9 cubic centimetres of serum injected. At 8 P.M. the temperature commenced to fall, and four hours later it reached  $95.4^{\circ}$  F. Convalescence was rather protracted, though this was probably the result of concomitant conditions. The man gave a history of syphilis and had Bright's disease, dating back at least four years.

CASE V.—Girl, aged eight years; pneumonia of right lower lobe; symptoms of moderate severity, temperature ranging between  $102.5^{\circ}$  and  $103.5^{\circ}$  F. On the third day 2 cubic centimetres of serum injected. The temperature maintained its usual range for twenty-four hours, when it commenced to fall, and by twelve hours later had reached normal. The pneumonia was followed by a trifling pleural effusion without any return of fever, but this was quickly absorbed and scarcely at all retarded convalescence.

CASE VI.—In Presbyterian Hospital. Man, aged twenty-four years; pneumonia of right upper lobe; general symptoms of pronounced severity, verging on the typhoid state, temperature ranging between  $103^{\circ}$  and  $105^{\circ}$  F. On the fifth day, at 8.30 A.M., 25 cubic centimetres of serum injected. By midnight the tempera-

ture had fallen to  $100^{\circ}$  F., delirium had disappeared, skin was cool and moist, and, in short, the general condition was immensely bettered. After this the temperature slowly rose, ranging between  $101^{\circ}$  and  $103^{\circ}$  F., but never attaining its previous maximum, and the delirium and other bad symptoms returned in a measure. It is perhaps worthy of note that during this period cold sponging produced a marked temporary abatement of the fever, while previous to the injection it had but little effect. Through an inadvertence no further injection was given till the eighth day, when 5 cubic centimetres of serum were used. Promptly after this the temperature fell to  $97^{\circ}$  F. Convalescence was very rapid.

CASE VII.—In Presbyterian Hospital. Boy, aged eleven years; case of moderate severity, temperature ranging between  $102^{\circ}$  and  $104^{\circ}$  F. On the fourth day, at 2.30 P.M., 11 cubic centimetres of serum injected. By 2 A.M. of the next day the temperature had fallen to  $96.8^{\circ}$  F. Convalescence was rapid.

CASE VIII.—In Philadelphia Hospital. Man, aged twenty-eight years; pneumonia of left lower lobe; symptoms of moderate severity, temperature averaging about  $103^{\circ}$  F.; diplococci in sputum. On the fifth day 25 cubic centimetres of serum injected. Twelve hours after the injection the temperature had fallen to normal.

CASE IX.—Man, aged twenty-one years; pneumonia of right lower lobe. This case was seen from the very inception of the disease, and promised in the beginning to be one of only moderate severity. On the second day, at 9 P.M. (forty-six hours after the initial chill), 25 cubic centimetres of serum were injected. The temperature up to this point had been constant at  $104.4^{\circ}$  F. At 9 A.M. of the following day it was  $103.4^{\circ}$  F., where it continued throughout that day, with no change in the general symptoms from those of the day preceding. At 9 P.M. 40 cubic centimetres more were injected. Twelve hours later the temperature had returned to its original  $104.4^{\circ}$  F. At 9 P.M. again on that day—the fourth of the disease—45 cubic centimetres were injected. Five hours later the temperature had fallen to  $101^{\circ}$  F., but this subsidence was only temporary and unattended by any amelioration of the general symptoms, which had been steadily growing graver. Two days later meningeal symptoms became prominent (before this there had been but the ordinary delirium of pneumonia or any other febrile state), and on the following day he died. At the time of death the temperature had reached  $108^{\circ}$  F.

CASE X.—In St. Agnes Hospital. Man, aged twenty-five years; upper lobe of right lung completely consolidated; all the symptoms were of pronounced severity; diplococci in the sputum; temperature ranged between  $102^{\circ}$  and  $104^{\circ}$  F.; immediately after admission to the hospital it had been  $105^{\circ}$  F. At the end of the fifth day 50 centimetres of serum injected. No appreciable effect was produced upon the symptoms by the injection, and the man died twenty-four hours later, the temperature at the time of death being  $104^{\circ}$  F.

CASE XI.—In Presbyterian Hospital. Woman, aged forty-five years; consolidation had involved whole of right lung; the symptoms were of the gravest possible character; temperature ranged between  $102.8^{\circ}$  and  $103.6^{\circ}$  F.; diplococci in sputum. On the sixth day, at 11.40 A.M., 30 cubic centimetres of serum injected. This was followed promptly by a rise of temperature to  $104.4^{\circ}$  F. Then it fell, reaching in fifteen hours  $101^{\circ}$  F., with a most gratifying change in the general condition. After this the temperature was irregular, ranging between  $101^{\circ}$  and  $104^{\circ}$  F., but it was thought that the symptoms lacked the extreme gravity of the period before the injection. It was not till the eleventh day that convalescence, which was afterwards moderately rapid, actually set in.

CASE XII.—Woman, aged forty-eight years; pneumonia of left lower lobe; symptoms of rather pronounced severity, temperature ranging between  $103^{\circ}$  and  $104^{\circ}$  F. On the sixth day 25 cubic centimetres of serum were injected, and a like quantity on the seventh day. Absolutely no effect was produced by the injections upon either the temperature or the general condition. The crisis occurred on the tenth day, and convalescence was probably rather more rapid than the gravity of the attack would have warranted.

CASE XIII.—In Philadelphia Hospital. Man, aged fifty years; pneumonia of right lower lobe; condition not at all good; diplococci in sputum. On the fifth day 15 cubic centimetres of serum injected. On the sixth day injection repeated, this time 25 cubic centimetres being used. Neither injection had any effect upon the temperature. Crisis occurred on the ninth day. From the time of the last injection the man complained of pain and soreness at its site,—on the outer aspect of the thigh. This spot afterwards became inflamed, indurated, and eventually the seat of an abscess, which was extremely slow in healing. There was no evidence of any systemic involvement from this abscess, and convalescence from the pneu-

monia went on uninfluenced by its occurrence.

CASE XIV.—In Philadelphia Hospital. Man, aged thirty years; alcoholic pneumonia; symptoms of extreme gravity, temperature ranging between  $101^{\circ}$  and  $102^{\circ}$  F.; diplococci in sputum. On the fourth day, at 4 P.M., 25 cubic centimetres of serum injected. Twelve hours later the temperature had dropped to  $100^{\circ}$  F., where it remained till 8 P.M. of that day (the fifth of the disease), when 17 cubic centimetres were injected. Six hours later the temperature had fallen to  $99.4^{\circ}$  F. For the next two days it ranged between  $99^{\circ}$  and  $100^{\circ}$  F., then it rose rapidly and the man died, the temperature at the moment of death being  $108.2^{\circ}$  F. No effect whatever upon the general condition had accompanied the lowering of the temperature following the injections. A short time before death a marked discoloration developed about the site of the second injection, persisting even after death.

Now, what deductions can be drawn from this series of cases? In the light of our experience with the first case injected, together with the results in other published cases, we must confess to a most distinct disappointment. In Cases I. to X. the serum used was apparently as perfect for its purpose as could be wished. It would be a useless expenditure of space and time to particularize the cases whence the serum was obtained; a careful study of them has enabled us to formulate no rules governing its irregularity of action. Suffice it to say that they were all cases of undoubted and typical pneumonia, in every one of which the presence of virulent diplococci had been established. In none of them was the interval which was permitted to elapse between the crisis and the taking of the serum more than two weeks; in many of them it was less. Having these serums, then, obtained under identical circumstances, it was surely to be expected that perfectly regular and definite results would follow their use, but the event proved otherwise. While some of the cases were marked successes, others showed equally pronounced failures. Thus, of the ten cases, only five can be claimed as distinctly proving any effect due to immune serum. In another (Case V.), while a crisis did occur following the injection, yet the time that elapsed before its completion (thirty-six hours) renders it doubtful that this effect was due to the serum, and the fact that an early crisis is not at all uncommon in children strengthens this doubt.

Of the three cases where no result was shown, in Case I. we are tempted to attribute

the at least partial failure to the fact that it was in a negro. Seeing that the diplococci in a negro's sputum seem to be so distinctly more virulent than those in the sputum of a white man, it may be imagined that the same holds good in the lungs, and that a larger dose of antidote would be required. It is possible that, had the first dose been larger or been followed by others, a conclusive result would have been obtained. It seems to be a fact, judging from experiments upon lower animals, that the more virulent the bacteria the less easily antiodoted is their toxine. But if the failure here was due to exceptional virulence of bacteria and consequently large amounts of toxine, we should expect an exceptionally pronounced immunity, granting that toxins have anything to do with immunity; and yet, as will be seen later, the serum of this man rapidly lost its antitoxic power. Case III. may be explained by the seeming irregularity of the pneumonia, though, on the other hand, diplococci—that crucial test—were present in abundance. From a careful study of the case, in the light of the symptoms and of the post-mortem examination, I am strongly of the opinion that such explanation is not sufficient, and the case must be classed as an unquestioned failure. In Case IX. no explanation whatever of the failure can be offered. Everything was favorable to the action of the serum. The man came under observation immediately after the initial chill, the general treatment was carried out under most favorable auspices, the quantity of serum used (110 cubic centimetres) was certainly large enough, and yet blank failure resulted: immune serum did not antidote the toxine.

Can we reconcile these discrepancies? It would seem not in the present state of our knowledge. That the irregular results were due to causes inherent in the persons of those injected, essential variations in disease processes, or subtle radical differences in constitution, and not to faulty conditions of the serum, is proved by the fact that different results attended the use of the same serum. Thus, Cases II. and III. had the same serum; II. was a success, III. a failure. Again, Case IV. showed a pronounced success, V. a doubtful result.

The lack of action of immune serum in certain cases might be explained on the assumption (1) of a duality of diplococci causative of pneumonia, (2) of a variation in the toxins, (3) of the inadequacy of the antitoxic theory to fully explain the cure of pneumonia and the subsequent immunity.

1. *The Duality of the Diplococci.*—While we are still not perfectly familiar with the life his-

tory of the specific cause of pneumonia, yet what work has been done and comparison with other specific diseases render this hypothesis only remotely probable.

2. *Variation in the Toxines.*—Bacteria, in the course of their growth, produce at least three distinct classes of poisons, the individual action of which is not definitely understood. These toxins being somehow instrumental in the production of the fever, it is on their neutralization or disappearance that the end of the fever depends. But these toxins are constant concomitants of the growth of bacteria, and while, under differing conditions of inherent qualities or environment, it is possible that the toxins are secreted in varying proportions, yet it is not likely that the average proportions would ever be so rudely disturbed as to lead to total failure of a neutralizing agent to act. The toxins must always be the same. It requires too violent a stretch of the imagination to conceive that under practically identical conditions of production in some few aberrant cases an entirely unusual toxin had been substituted. Therefore this hypothesis is not to be entertained; and this, then, brings us to consider,—

3. *The Inadequacy of the Antitoxic Theory.*—This theory proposes a purely chemical action, and, granting that there is a single specific cause for pneumonia and that the toxins produced are always the same, if there be a definite antipneumotoxine, must not its action be the same in all cases? Let us draw attention here again to the probable difference between cure and immunity. Cure, or the disappearance of fever, means the destruction of the fever-producing toxins; immunity, the impossibility of bacterial growth or failure of secreted toxins to produce deleterious effects. Are these two cases necessarily identical? We are driven to the conclusion by consideration of these cases reported that they are not; the neutralization is merely a step in the production of immunity, and its causes will have to be sought deeper down. At the same time there may be a neutralization of poison by substances in the immune serum, but these substances may exist only in the serum and not in the plasma, and really not be concerned in the production of immunity.

While, therefore, it cannot be doubted that immune serum may have a most pronounced effect, yet the irregularity of its action certainly suggests strongly that there are important factors other than the antipneumotoxine concerned in the production of the crisis and the subsequent immunity. What these factors may be it is impossible to indicate, but it would seem

probable that they are to be found rather in some condition of the cells than of the blood-serum.

One thing in these experiments we have been most certainly unable to do,—that is, to duplicate the results published by several observers obtained by very small quantities of serum. In the only case where we ventured to use so small quantity as 2 cubic centimetres (that of the child, where surely a small quantity would be most likely to be sufficient), the result was practically negative.

We have considered hitherto only the first ten cases, where only perfect serum was used; the other cases were injected with serum which might be supposed *a priori* to have a less definite effect. In Cases XI. and XII., and in the first injection in Cases XIII. and XIV., the serum was obtained from a case of abortive pneumonia, the crisis having occurred on the third day. The case was one of unquestioned pneumonia, diplococci being present in great abundance in the sputum. Such abortive pneumonia can be best explained by the incidence of pneumonia on a case almost but not quite immune naturally, and were the antitoxic theory correct, one should expect a most marked effect, instead of which the results were all purely negative, except in Case XI., where the result was at least doubtful. This would bear out what has previously been found to be the fact, that naturally immune serum does not protect, and strengthen the hypothesis of different methods for the production of immunity.

In Cases XIII. and XIV. the serum used was obtained from Case I. (the negro) five weeks after his crisis. Within two weeks after his crisis he had been bled and the serum used with a successful result, but in these two cases the result was negative. Therefore, if these two cases prove anything, serum which was at first actively protective may lose its antitoxic power after the lapse of five weeks.

From a therapeutic stand-point the results of the injections are disappointing. In the ten cases where perfect serum was used there were three deaths. As this is about the ordinary death-rate in pneumonia, as a treatment purely of pneumonia serum injection would scarcely commend itself. With the imperfect serum the death-rate was about the same,—one in four.

The injections are, however, if carried out with proper precautions, perfectly harmless. In none of the cases, either of pneumonia or typhoid fever, were any bad general effects noted. In two cases (XIII. and XIV.) there was local inflammation following the injection, but as the serum used was obtained from one

man at the same time, and as, owing to the fact that it was not obtained under our personal supervision, it was in all probability contaminated, this result might have been avoided. One word of caution here about the serum: it must not be obtained from a case where there is any suspicion of kidney-lesion, for we have found\* that serum drawn from victims of Bright's disease is capable, when introduced intravenously into dogs, of producing nephritis.

*Typhoid Fever.*—Stern† has found that white mice injected with a mixture of typhoid bouillon with serum from a recent convalescent from typhoid fever survive, while those treated with unmixed bouillon die. This would seem to indicate some antidotal properties in the serum. Though it is scarcely to be supposed that from two diseases so dissimilar as typhoid fever and pneumonia the same result would be obtained by the injection of immune serum, yet the following experiments were undertaken with the hope that some effect would become apparent. The serum obtained was from convalescents in whom somewhat less than two weeks had elapsed since the end of the fever. It was obtained by means of venesection.

CASE I.—In Philadelphia Hospital. Man, aged thirty years; case of average severity; mild nocturnal delirium; bowels moderately constipated; heart strength well preserved. The history and symptoms pointed to the ninth day as the day on which he came under observation. The temperature would have ranged probably between 102° and 104° F., but sponging and bathing kept it between 100° and 103° F. On the twelfth day, at 7.15 P.M., 60 cubic centimetres of serum were injected. At midnight, after sponging, the temperature was 98.4° F.; previous to the injection it had never been reduced by sponging or bathing below 100° F. This seemed to inaugurate the gradual defervescence of the temperature. On the fifteenth day it reached normal in the morning, and from the twenty-second day on it was permanently practically normal. Convalescence was rapid.

CASE II.—In Philadelphia Hospital. Boy, aged nineteen years; first seen on seventh day; light case; very slight nocturnal delirium; two or three stools a day; heart quite weak; temperature ranged between 100° and 102° F. On the twelfth day, at 7 P.M., 20 cubic centi-

\* Boylston Prize Essay, to be published in the American Journal of the Medical Sciences.

† *Deutsche Med. Wochenschrift*, September 15, 1892.

metres of serum injected. 11 A.M. next day temperature  $98.4^{\circ}$  F.; then it rose to  $101^{\circ}$  F. Injected again at 5.15 P.M. 20 cubic centimetres. 2 A.M. next day temperature  $98.4^{\circ}$  F.; then it rose till at 6 P.M. it was  $100.4^{\circ}$  F., when he was again injected with 20 cubic centimetres of serum. After this the temperature rose till at 9 P.M. it was  $101.8^{\circ}$  F. It slowly settled after that, and convalescence set in on the eighteenth day.

CASE III.—In Philadelphia Hospital. Boy, aged eighteen years; came under observation on the eighth day; case graver than the preceding; quite marked delirium; heart rather weak; very slight diarrhoea; temperature ranged between  $102^{\circ}$  and  $104^{\circ}$  F., but could be depressed to  $99^{\circ}$  F. by sponging. Injected as follows: twelfth day, 10 cubic centimetres of serum; thirteenth day, 10 cubic centimetres; fourteenth day, 25 cubic centimetres. No effect was apparent on the temperature till the fifteenth day, when it ranged between  $100^{\circ}$  and  $101.8^{\circ}$  F. It gradually fell after that, remaining at normal from the twentieth day on.

These cases were none of them especially grave, and would certainly have recovered in the natural course of events. The type of typhoid fever prevalent was mild and irregular, and these cases were selected as being the gravest and most typical obtainable at that particular time. Some of the companion cases ended as early as the end of the third week, and it may be that the cases above recorded ran a normal course uninfluenced by the injections. Still, it is unusual to have three consecutive cases of typhoid fever terminate as these did on the twenty-second, eighteenth, and twentieth days respectively. If the serum had any immunizing effect, it acted as would have been expected, not by producing any sudden fall of temperature, but by bringing on the gradual termination of the fever sooner than it would otherwise have occurred. In spite, then, of the mild nature of the cases and the somewhat irregular action of the serum, we are inclined to the opinion that the serum had some effect. It is unfortunate that it could not have been tried upon some severe cases.

It affords us great pleasure to express our thanks to Drs. J. H. Musser, D. F. Woods, and J. P. C. Griffith for their kindness in placing at our disposal cases of pneumonia under their care in the Presbyterian and St. Agnes Hospitals, and to the resident staff of the Philadelphia, Presbyterian, and St. Agnes Hospitals for assistance in the observation of the cases.

## THE PHYSIOLOGICAL ACTIONS OF ALCOHOL.

ABSTRACT OF A PAPER PRESENTED TO THE SECTION ON THERAPEUTICS OF THE FIRST PAN-AMERICAN MEDICAL CONGRESS, HELD AT WASHINGTON, D. C., SEPTEMBER 5, 6, 7, AND 8, 1893.

BY DAVID CERNA, M.D., PH.D.,

Demonstrator of Physiology and Lecturer on the History of Medicine in the Medical Department of the University of Texas; formerly Demonstrator and Lecturer on Experimental Therapeutics in the University of Pennsylvania; Spanish-speaking Secretary (Section on Therapeutics) of the First Pan-American Medical Congress, etc.

(Concluded from page 309.)

### ON DIGESTION.

IT is almost an established fact that alcohol in small doses aids the process of digestion. This may not be an absolute rule, but it certainly holds good in the large majority of cases.

It is true that some observers deny to alcohol any such action, but on examining the clinical literature of this part of the subject (which is certainly, to say the least, an extensive one), it is found that those who uphold this latter view form the minority.

Buchner,\* from the results of a series of experiments, comes to the conclusion that ten per cent. of alcohol does not affect artificial digestion, while beer, even when used in dilute form, retards the process. His assertions, however, have not been absolutely confirmed. It is true that Gluzinski,† who gave the drug to fasting individuals, found that digestion, as influenced by alcohol, may be divided, in the case of healthy persons, into two phases: the first characterized by marked retardation of proteid digestion, the nitrogenous materials failing to be changed into peptones until the alcohol was removed; the second stage beginning after the removal of the drug, when the secretion of gastric juice is so abundant that in the end the food is digested as soon or sooner than if no alcohol had been administered.

On the other hand, Mohilansky‡ affirms that alcohol, taken in small quantities, distinctly improves the appetite and gives rise to a marked increase in the assimilation of the nitrogenous constituents of food, this increased assimilation being due to a more complete absorption and intensified gastric digestion, resulting, as has been stated elsewhere, from a prolonged retention of food in the stomach on the one hand, and from increased digestive power and secretion of the gastric juice on the

\* *Deutsch. Archiv f. Klin. Med.*, Bd. xxi. S. 537.

† *Ibid.*, and *Annual of the Universal Medical Sciences*, 1888.

‡ *Loc. cit.*

other. Blumenau\* has arrived at similar conclusions. This investigator, with the view of studying the action of alcohol on the functions of the stomach, made a series of experiments upon five healthy individuals, aged from twenty-two to twenty-four. The observations were made in the clinic of Koshlakoff, of St. Petersburg. The drug was given from ten to twenty minutes before dinner, in doses of 100 cubic centimetres ( $3\frac{1}{2}$  ounces), and in the form of solutions of the strength of from twenty-five to fifty per cent. The meals allowed consisted of from 500 to 600 grammes (16 ounces) of soup, a cutlet weighing 90 or 100 grammes ( $2\frac{1}{2}$  to 3 ounces), and 200 or 250 grammes (6 to 8 ounces) of wheat bread. The author found that during the first three hours after the ingestion of the alcohol the gastric digestion is distinctly retarded, which is caused by a marked diminution of the digestive power of the gastric juice. The diminution is dependent upon the decreased proportion of hydrochloric acid and the general acidity of the gastric juice; this acidity is almost entirely produced by lactic acid. In habitual drinkers the changes are less pronounced than in alcohol abstainers. All other conditions being equal, strong solutions of alcohol give rise to more intense changes than weak ones. The investigator found, further, that during the fourth, fifth, and sixth hours after meals the gastric digestion becomes considerably more energetic, the general acidity of the juice rises from .22 to .35 per cent., and the proportion of hydrochloric acid increases, to reach its maximum (from .12 to .14 per cent.) by the end of five hours after meals, while the lactic acid amount decreases correspondingly, attaining its minimum about the same time, when the acid either gives but a very faint reaction or altogether ceases to give any reaction. Corresponding to the alterations, the gastric juice during the second stage acquires a far higher digestive power. Under the influence of alcohol, the secretion of the gastric juice becomes more profuse and lasts longer than without alcohol. During the first hour the action of pepsin seems to be slightly decreased, because, on adding rennet to cow's milk, it coagulates more slowly than in subsequent hours. In regard to the motor power of the stomach, such was ascertained to be somewhat decreased, as tested by the internal administration of salol, according to the method of Ewald. The same may be said in regard to the absorptive power of the organ, in which

case the decrease was determined by the administration of the iodide of potassium. It was found that the intensity of the alteration in the motor and absorbing powers of the stomach corresponds to the concentration of the alcoholic solutions employed.

Of course, in large amounts alcohol hinders digestion very decidedly, and the continuous use of the drug causes pathological changes of varied nature, the principal one of which is that produced upon the liver. That alcohol is a powerful factor in the production of hepatic cirrhosis there is scarcely any doubt. This has recently been confirmed by the results obtained by De Rechter† in an experimental research. The investigator made a series of experiments on dogs and rabbits. After having ascertained the amount of alcohol used by hard drinkers, he administered to the animals employed a mixture consisting of 22.5 parts of ethylic alcohol at 96° F., 2.5 parts of methylic alcohol, and 75 parts of water. Of the ten rabbits and four dogs used, one dog and four rabbits lived long enough to be of use to the experimenter; in the rabbits he found cirrhosis in the portal spaces. In places, bands of connective tissue were found uniting the portal vein with the sublobular veins, but the parenchyma of the organ was everywhere free from change. In the dog there was cirrhosis occupying the sublobular veins, where alcoholic cirrhosis is said by Sabourin to commence in man. De Rechter attributes this difference in development to some modifying influence of the alcohol exercised by the liver of the rabbit. If experimenters have found fatty and cirrhotic change in many cases, the author attributes it to the fact that they used alcohol too short a time and in too large doses.

Be all the results of these researches as they may, certain it is that in the test-tube the digestion of food is retarded or inhibited by the addition of alcohol; yet, in the stomach, on the contrary, alcohol aids digestion, not, perhaps, through any inherent powers of its own, but mainly by virtue of its irritant and stimulating properties, inducing in this manner an increased amount of gastric juice.

#### ON THE URINARY SECRETION.

How alcohol affects the urinary secretion has not been definitely determined. Mohilansky‡ found that the drug, in healthy people, does not possess any diuretic action; but that, on the contrary, it rather tends to inhibit the

\* *Wratsch*, No. 42, 1889, and *Med. Chronicle*, January, 1889.

† *La Presse Médicale de Belge*, June 19, 1892.

‡ *Loc. cit.*

elimination of water by the kidney. Diametrically opposed to this statement is that of Diakonoff,\* who observed that alcohol, in febrile patients, considerably increased the daily quantity of urine, markedly suppressing at the same time the aqueous loss through the lungs and by the skin.

From a few experiments performed upon myself, I have noticed that small quantities of alcohol almost always cause an increase in the daily amount of urine secreted. The action under consideration, however, cannot be accurately ascertained, since it must depend not only upon the amount of alcohol ingested, but also upon the condition of the individual, whether this be in a healthy or a febrile state.

It is not at all improbable that if, in a healthy person, the amount of alcohol administered be sufficient to stimulate the circulation, a corresponding activity of the kidneys would be obtained as a consequence of the generally increased arterial pressure. On the other hand, since alcohol in large doses, as has been noticed, tends to markedly decrease the arterial pressure, accompanied by a probable dilatation of the cutaneous blood-vessels, according to Mohilansky, it would naturally be expected that such a phenomenon would favor perspiration and thus interfere with the renal secretion.

The same results might be witnessed in febrile conditions, in which, as has been observed by Diakonoff, the drug, by causing a suppression of watery excretion through the lungs and skin, and undoubtedly a stimulation of the general circulation, produces a marked increase in the daily amount of urine secreted. The question, in the present state of our knowledge of this part of the subject, remains unanswered one way or the other.

#### WHAT BECOMES OF ALCOHOL IN THE ANIMAL ECONOMY?

The last point which I propose to discuss in this paper is that relating to the fate (as the French would have it) of alcohol in the animal economy. This subject naturally deals with the elimination of the drug. Is alcohol eliminated as such, or does it undergo oxidation, as is maintained by a probable majority of writers upon this question? This is certainly of paramount importance, for here lies the basis of the value or the harmfulness or unnecessary use of alcohol in the treatment of disease. Again, not only may it be asked, Is alcohol a general stimulant? but also, Does the

drug likewise serve the purpose of a food? These questions, although long-mooted ones, deserve the most careful consideration.

It has for a long time been held that alcohol is completely, or nearly so, burnt up in the system. But in the celebrated work of Duroy, Lallemand, and Perrin it is stated by these authors that alcohol is eliminated unchanged, basing their assertion on the fact that they could not find in the blood or in the tissues the products of alcohol oxidation, such as acetic acid and aldehyde; and on the fact, also, that they found the alcohol unchanged in the expired air, in the urine, and in the sweat. These authors relied on the chromic-acid test, which is said by Binz† to be fallacious. Binz, assisted by Stenbach and Schmidt, in a series of experiments, could not detect alcohol in the breath, affirming, therefore, that no drug was expelled by the lungs. He attributed the odor noticed in the breath of heavy drinkers to the ethers and other volatile principles of the various liquids ingested.

Baudot‡ also questioned the correctness of the statements of Duroy and Perrin, on the ground that the chromic-acid test is so delicate as to reveal the presence of .165 of a grain in a quart of water. He further noticed, in twenty experiments performed, that, unless it be ingested in enormous amounts, alcohol is practically not eliminated by the urine. These results have been confirmed later by the researches of other investigators, as Anstie,§ Schulinus,|| and Lieben.¶ Schulinus showed that only very small quantities of alcohol pass through the kidneys, the largest portion of the drug taken into the blood finding its way into the tissues and organs by exosmosis; and in a number of experiments he found that one-fourth of the alcohol administered had disappeared from the body after from two hours to three hours and fifteen minutes. From the fact, again, that only a trifling amount of the drug was eliminated by the kidney, the author arrived at the conclusion that the alcohol given must have been burnt up in the system. The same conclusions are formulated by Lieben and Anstie. This latter investigator detected a small quantity of alcohol escaping from the lungs.

\*\* *Loc. cit.*

\* *Loc. cit.*

and later in 1866, in collaboration with Dupré,\* carried on two elaborate researches on the same subject. In the first investigation the experiments were performed upon thirty-three men, to whom he administered four thousand grammes of alcohol. The drug was recovered from the urine of all the men by repeated distillation, in order to avoid the fallacies of the chromic-acid test. In this manner the experimenter obtained from the urine, within six hours after the ingestion of the drug, only .25 per cent. of the amount of alcohol given. Identical and perhaps more accurate results were obtained by the same observer in his second investigation. In this instance greater care was taken to avoid loss during distillation, and he then recovered from the urine .82 per cent. of the alcohol administered.

This experimentation was repeated by Subbotin† on six rabbits. This investigator claims to have demonstrated that the elimination of alcohol continues for a longer period than is generally believed, and that twice as much of the drug escapes through the skin and lungs as by the kidneys. His results, however, do not disprove those of the observers just mentioned, since he employed very large amounts of alcohol, in which case the elimination must be in direct proportion to the quantity ingested, for certainly a limit to the powers of the system to oxidize alcohol must be expected.

In a series of experiments, Edes‡ observed that elimination of alcohol is greater by the lungs than by the kidneys, after small amounts, the contrary taking place under large doses of the drug. Not much weight, perhaps, can be attached to these statements, from the fact that the author relied chiefly on the chromic-acid test. But Anstie,§ in a second series of experiments upon dogs, using the method employed by Subbotin, confirmed the results obtained in his (Anstie's) first investigation. He found but a very trifling amount of alcohol left in the body. Similar results have been obtained by Bodländer|| from experiments performed upon himself and on dogs. His studies have been repeated and his observations apparently confirmed by Wöhler.¶ Bodländer found, by experiments on himself, that elimination

occurred by the kidneys to the extent of 1.2 per cent. and by the lungs to 1.6 per cent. of the amount of alcohol ingested. In the dog, he recovered from the urine 1.6 per cent. and from the breath two per cent. No alcohol was detected by this experimenter in the intestinal excretions, nor in the milk of a goat to which nearly a quart of brandy had been administered.

It was first discovered by Lieben,\*\* and afterwards by Dupré†† and Bechamp,‡‡ that a body closely resembling alcohol occurs in the urine of habitual abstainers. Indeed, Bechamp was able to get from the urine of persons who had not taken the drug in any form for a long time alcohol in sufficient quantities to burn it. Lieben found the same substance also in the urine of the dog, the horse, and the lion, and Rajewski§§ in that of the rabbit.

It seems to have been proved, from the results of the foregoing experiments, that alcohol exists in the healthy organism, and therefore the detection of the drug in the different secretions and excretions, after its ingestion, is no proof that alcohol does not undergo oxidation in the economy. It is true that so far no products of oxidation have been found in the blood, but in this case it is reasonable to suppose that the process of oxidation goes on continuously, without interruption, until the production of water and carbon dioxide occurs as the ultimate result of such oxidation.

The elaborate and excellent researches of Ford||| tend to confirm the theory of the oxidation of alcohol in the animal economy. This investigator studied the subject on the supposition that the sugar manufactured by the liver must, before its final destruction and conversion into carbon dioxide and water, be changed into alcohol. This in mind, he carefully examined large quantities of blood of animals, seeking to obtain alcohol from that fluid by a process of repeated distillation. To prove that the substance obtained from blood in this manner was alcohol, the author employed the chromic-acid test, and relied also on the inflammability peculiar to alcohol, and similarly on the optical appearance of this substance in the conducting tube at the time the distillate began to boil. Again, to prevent possible oxidation of the alcohol during this delicate process, Ford sometimes added sulphuretted hydrogen.

The experimenter then proceeded to examine

various other tissues as substances to be distilled, and here he based his calculations on the amount of carbon taken in and that exhaled, especially in regard to the quantity of alcohol to be found in the blood of the pulmonary capillaries. Thus he determined the quantity of alcohol respectively from the capillary blood of the lungs, from fresh lung-tissue, from putrescent lung-tissue, from fresh thoracic blood, from putrescent thoracic blood, from fresh liver-tissue, and from putrescent liver-tissue.

An examination of the figures given in Ford's original table reveals the interesting and important fact that the smallest quantity of alcohol was obtained from fresh liver-tissue and the greatest amount from putrescent liver-tissue. This appears to show that in the latter instance the glycogen must have undergone fermentation. The same is seen in regard to the quantity of alcohol extracted from fresh and from putrescent thoracic blood.

An unbiased examination of all the preceding investigations appears to clearly demonstrate that but a very small quantity of alcohol is eliminated as such from the organism. The drug must, therefore, be oxidized in the body, thus serving the purpose of a food and in this manner generating force. This is the case, according to Dupré,\* who has shown that one gramme of alcohol oxidized in the organism yields 7184 heat-units, while the same weight of lean beef evolves 1482 heat-units only. The inference is obvious. Further estimates have demonstrated that two ounces of alcohol generates a force equal to that generated by a little over nine ounces of lean beef, this latter being sufficient to maintain the circulation and respiration of an ordinary adult man per day. The results of these calculations seem to be supported by the able experiments of Reichert.†

It must, therefore, be concluded that alcohol, so far as our clinical and experimental knowledge goes, is mainly destroyed in the system, generating vital force, and that it ought to be considered as a food.

#### CONCLUSIONS.

I shall now, to close this imperfect study of the actions of alcohol, give a summary of the conclusions which I have been able to draw, and which will be found scattered throughout the preceding pages. They are as follows:

1. Alcohol in small amounts excites and in

large doses depresses both the peripheral motor and sensory nerves.

2. Excessive quantities cause a spiral degeneration of the axis-cylinder of nerve-fibres.

3. Reflex action is at first increased and afterwards diminished by an influence exercised by the drug upon the spinal cord and the nerves.

4. In small amounts the drug stimulates the cerebral functions; it afterwards, especially in large quantities, depresses and finally abolishes them.

5. Alcohol causes lack of co-ordination by depressing both the brain and the spinal cord.

6. In toxic doses alcohol produces hyperæmia of both brain and spinal cord, especially of the lumbar enlargement of the latter.

7. Small doses of alcohol produce increased rapidity of the cardiac beat; large amounts, a depression of the same. In either case the effect is brought about mainly through a direct cardiac action.

8. The drug in small quantities causes a rise of the arterial pressure by a direct action upon the heart; in large amounts it depresses the arterial pressure similarly through a cardiac influence.

9. In large doses alcohol enhances coagulation of the blood; in toxic quantities it destroys the ozonizing power of this fluid, causing a separation of the hæmoglobin from the corpuscles.

10. Alcohol in small doses has little or no effect on the respiratory function; in large amounts it produces a depression of both rate and depth of the respiration through a direct action on the centres in the medulla oblongata.

11. The drug kills by failure of the respiration.

12. On the elimination of carbon dioxide alcohol exercises a varying action, sometimes increasing, sometimes decreasing, such elimination.

13. The action of alcohol on the amount of oxygen absorbed also varies and may be said to be practically unknown.

14. The drug lessens the excretion of tissue-waste, both in health and disease.

15. In small amounts alcohol increases the bodily temperature; in large doses it diminishes the same. The fall of bodily temperature is due mainly to an excess of heat dissipation caused by the drug.

16. Alcohol, in sufficiently large amounts, has a decided antipyretic action.

17. In moderate amounts alcohol aids the digestive processes.

\* *Practitioner*, vol. ix. p. 33, 1872.

† *Loc. cit.*

18. Alcohol diminishes the absorption of fats.

19. The drug exercises a varying influence on the amount of urine secreted, but it probably increases the activity of the kidneys.

20. In large doses, or when continuously used for a long time, alcohol produces cirrhotic changes of hepatic especially and paralysis of spinal origin. It also causes insanity, epilepsy, and other maladies.

21. Alcohol is mainly burnt up in the system when taken in moderate quantities, but when ingested in excessive amounts it is partly eliminated by the breath, the kidneys, and the intestines.

22. Alcohol is a conservator of tissue, a generator of vital force, and may therefore be considered as a food.

UNIVERSITY OF TEXAS, GALVESTON.

### *NATURE, DIAGNOSIS, AND TREATMENT OF PERNICIOUS ANÆMIA.*

READ BEFORE THE PHILADELPHIA COUNTY MEDICAL SOCIETY,  
MAY 9, 1894.

BY ALFRED STENGEL, M.D.,

Instructor in Clinical Medicine, University of Pennsylvania; Assistant Physician to the University Hospital.

WE cannot approach the study of pernicious anæmia in an intelligent manner without first of all determining exactly what group of cases we are to consider under this head; and we shall find that the vagueness of the term has led to not a few misconceptions regarding the natural history, the prognosis, and even the treatment of the disease. The concise and, to this day, most accurate description of the principal features of what we regard as pernicious anæmia, published by Addison in 1843, and more particularly ten years later, is one of the striking evidences of the keenness of this great physician's power of observation. "For a long period," he says, "I had from time to time met with a very remarkable form of general anæmia occurring without any discoverable cause whatever,—cases in which there had been no previous loss of blood, no exhausting diarrhoea, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous, or malignant disease." And further on, "It makes its approach in so slow and insidious a manner that the patient can hardly fix a date to the earliest feeling of that languor which is shortly to become so extreme. The countenance gets pale, the whites of the eyes become pearly, the general frame flabby rather than

wasted, the pulse perhaps large, but remarkably soft and compressible, and occasionally with a slight jerk, especially under the slightest excitement. There is an increasing indisposition to exertion, with an uncomfortable feeling of faintness or breathlessness on attempting it; the heart is readily made to palpitate; the whole surface of the body presents a blanched, smooth, and waxy appearance; the lips, tongue, and gums seem bloodless, the flabbiness of the solids increases, the appetite fails, extreme languor and faintness supervene; breathlessness and palpitations are produced by the most trifling exertion or emotion; some slight œdema is probably perceived about the ankles; the debility becomes extreme, the patient can no longer rise from bed, the mind occasionally wanders, he falls into a prostrate and half-torpid state, and at length expires; nevertheless, to the very last, and after a sickness of several months' duration, the bulkiness of the general frame and the amount of obesity often present a most striking contrast to the failure and exhaustion observable in every other respect." This stands to-day as a faithful and accurate account of the disease; but we have learned that the disease is not always as obscure in its causal relations as Addison believed.

From the stand-point of our present knowledge four groups of cases are clearly distinguishable. Leber, Gusserow, and Channing pointed out the unquestionable relation of pregnancy and lactation to a first group of cases; while in a second the influence of intestinal parasites was clearly demonstrated by Sangalli and other observers in Italy, and by Bäumler, Schönbachler, and others in Germany. More recently a third group of cases has been reported, by the investigations of Fenwick, Nothnagel, Litten, Kussmaul, Henry and Osler, Kinnicutt, and others, in which degenerations of the gastric mucosa play an important part, probably causative, in the disease. Other causes of a less immediate nature, perhaps predisposing, have been assigned, but at least these three groups are definitely known and admitted. There is left a certain number of cases in which no etiological factors are discoverable, but in which the clinical manifestations are practically identical. Is the pathogenesis in these last cases similar or the same as in the first-named groups, and shall we include all four classes under the head of pernicious anæmia? The answer to these questions will, I think, require a little consideration of the nature of the disease as we now know it.

The study of the blood in pernicious anæmia

shows as the most important feature the great reduction in the number of the red blood-corpuscles. In cases of moderate severity there may be 1,500,000 per cubic millimetre, in the most serious as few as 143,000, as Quincke observed the day before the death of one of his cases. This remarkable decrease in the number of red corpuscles must result either from decrease in the production of the red corpuscles, from increased destruction, or from a combination of the two. Now, I intend to show that in pernicious anæmia the important factor is hæmolytic, but that faulty hæmogenesis plays a part; that the gastro-intestinal tract is the seat of the destruction, or at least the source, of the hæmolytic agents; and, finally, that since the four above-named groups are similar in the condition of the blood, in the pathogenesis, and in their pathological tendency, it is more accurate scientifically to place them together as comprising the condition pernicious anæmia. Many modern writers place the apparently causeless cases apart as true "Addisonian pernicious anæmia," regarding the other cases as severe secondary anæmias; but there is much and good reason to believe that all cases are secondary, and there is a manifest advantage in practical medicine in holding to this view and regarding every case as one of obscure anæmia whose nature may be discoverable on close scrutiny. A rooted belief in the idiopathic or essential character of pernicious anæmia cannot but lead to neglect of careful search for hidden causes.

The later and, at the present day, most popular view of the origin of pernicious anæmia is that hæmolytic, or blood destruction, becomes increased beyond the powers of normal hæmogenesis to restore the blood. This view has been advocated by many writers, but none has done so much to bring it to the point of positive proof as Dr. William Hunter. The evidences of hæmolytic are found, in the first place, in the blood itself, in the numerous small, apparently fragmented, red corpuscles, in the decolorized corpuscles, showing merely the framework of the corpuscle, and, I believe, in the poikilocytes themselves. It is difficult to imagine these bodies as resulting from anything but destructive causes; but in themselves they would not constitute positive evidence. There are, however, resulting conditions which indicate the ultimate fate of the coloring-matter and other constituents of the blood-corpuscles after their disintegration. The most important of these, and one which, so far as we now know, is peculiar to pernicious

anæmia, is the deposit of iron-containing pigment in the outer zones of the hepatic lobules. This increase of iron in the liver was first observed by Quincke, and later by Rosenstein, Peters, Hunter, Burr and Griffith, Scott, and others, and in some of its features is perhaps characteristic of pernicious anæmia. It results, as Hunter has recently shown, not from the hæmolytic action of the liver itself, but from the storing up of the pigment matter after its liberation in other parts of the portal circulation. The yellow pigmentation of the skin and eyes is doubtless of similar nature. Not only is iron deposited in the liver in excessive quantity, but the amount discharged in the bile is generally increased, and the color of the urine has been found to be deepened by the presence of an altered form of urobilin. The fact that some cases do not show this increased color of the urine does not by any means diminish the importance of the observation when made. Destruction of white corpuscles, which their decreased number might lead us to suspect, is further evidenced, though not absolutely, by the excess of uric acid generally present in the urine; and it may well be that the fever of the disease is due to the same cause. Mott says that his experience warrants him in asserting "a constant relation between the pyrexia, the diminution in the red corpuscles, and the color of the urine." Finally, there is experimental evidence that pernicious anæmia may be the result of active hæmolytic, the anæmia resulting from injection of certain hæmolytic poisons, such as pyrogallol (Silbermann), into animals being strikingly like the natural disease as observed in man. These evidences I believe are sufficient to warrant the belief that hæmolytic plays a most important rôle in the pathogenesis of the condition under discussion.

The indications of faulty hæmogenesis are less numerous, though their existence cannot be doubted. In the first place, as Henry has pointed out, the large, flabby, ill-formed macrocytes of pernicious anæmia cannot but convey the impression that they result from some error in blood formation, and surely cannot be regarded as products of hæmolytic.\* With these must be ranked the nucleated red corpuscles, whose presence in the blood after hemorrhage, or after rapid blood destruction, is doubt-

\* Ehrlich has sought to show by their peculiar reaction to stains that they are degenerative in nature, but the studies of frog's blood by Gabritschewski indicate that the younger corpuscles present this peculiarity rather than the older and therefore more likely to be degenerated.

less an indication of partially unsuccessful efforts at restoration of the normal number of corpuscles. Finally, the lymphoid character of the bone marrow in pernicious anæmia is probably a consequence of the intense blood destruction, and results from the effort to supply corpuscles, as is the case, though to a less degree, in other forms of anæmia. Rindfleisch has studied this subject with particular care, and concludes that there is some obstacle in the way of the extrusion of red corpuscles from the hæmatoblasts of the marrow, which in consequence become greatly increased in number.

We have then, I believe, sufficient evidence to indicate that pernicious anæmia is both hæmolytic and hæmogenetic, but that the former process is the more important of the two.

As to the seat of the hæmolytic changes, we derive most information from those cases in which a distinct causal relation has been determined, and especially from the cases in which the gastro-intestinal tract is the seat of morbid lesions. Of the latter a great number has been recorded, though in some of the earlier cases the diagnosis of pernicious anæmia was not determined with the accuracy we could wish. Fenwick first pointed out a remarkable atrophy of the gastric mucosa and glands; Nothnagel observed cirrhotic contraction with disappearance of the glands; Nolen described a form of interstitial gastritis with atrophy of the glands; ulcers of the duodenum and stomach were found by Zahn and Litten; Homolle found simple duodenitis; while Banti, Sasaki, and others described changes in the sympathetic nerves and in the ganglia of the stomach walls. In the case of some of these lesions it may properly be urged, as has been done, that the anæmia was the cause of the gastric changes rather than the reverse; but in such instances as those of cirrhotic thickening of the stomach, with destruction of the mucosa, this explanation does not suffice. In a recent case under my own observation there was a history of marked gastric trouble for fifteen years, during which the patient remained in a fair state of health. Finally, the patient began to grow more anæmic, her blood and general appearance assumed the characters seen in pernicious anæmia; and on subsequent examination of the stomach a marked degree of cirrhosis, with partial destruction of the tubules, was discovered. Surely in a case of this kind the gastric lesions could not be regarded as secondary to the pernicious anæmia. The morbid conditions of the intestines with which pernicious anæmia has been found to be associated are similar to

those in the stomach; but attention has been directed more particularly to the influence exerted by intestinal parasites, particularly the *Bothriocephalus latus* and the *Anchylostomum duodenale*. In a few isolated cases other parasites were found,—*Ascaris lumbricoides* (Demme) and *Tenia saginata* (Eisenlohr),—but in these the diagnosis of pernicious anæmia is open to some doubt.

The manner in which these gastric and intestinal lesions bring about the anæmic condition of the blood must still be regarded as an open question, though we have undoubtedly reached a point where some measure of positiveness is justified. In the first place, it is, I believe, definitely ascertained that pernicious anæmia is a hæmolytic disease to a great degree, and that we cannot, therefore, regard the operation of the lesions described as being merely that of causes which interfere with proper nutrition. This may be a factor, but it is surely not the important one. Clinical observations and latterly experimental evidence, on the contrary, point to the development and action of poisonous substances within the intestinal tract, which by their hæmolytic action outrun the blood-making powers. A remarkable case of Sandoz may be cited in this connection. This observer records an instance of marked and progressive anæmia, in which there were prominent gastric symptoms and great fetor of the breath, and which showed decided improvement in the gastric conditions, the breath, and the anæmia after repeated lavage of the stomach. A similar case has recently been reported by Meyer. Jürgensen observed a similarly pertinent case, in which marked anæmia rapidly disappeared after administration of purges and the discharge of immense numbers of the *Bacterium termo*. The question of the relation of the animal parasites of the intestines to the anæmic condition is less easily determined than that of such organisms as bacteria, but there is much in favor of the view that it is by the generation of hæmolytic poisons, either in their natural growth or, as Schapiro claimed, from their death and decomposition. The belief that the anchylostomum causes anæmia by the abstraction of blood was attractive at first sight, but there are recorded cases of marked pernicious anæmia in which the worms were far too few to account for more than a trifling loss of blood. In addition, the discharge of the parasites is often followed by such rapid improvement in the symptoms that the conclusion that some source of intoxication has been removed seems well-nigh irresistible.

Finally, the important experiments of Hunter furnish additional evidence, in showing the active part the gastro-intestinal tracts may play in blood destruction when hæmolytic agents are administered. The poison employed by him was toluylendiamin. After injection of small doses the blood of the splenic vein alone showed hæmolytic changes; after large doses that of the mesenteric veins was also affected; and when the spleen had been removed, the chief hæmolysis was exercised in the intestinal circulation. Whether or not the spleen would play the secondary rôle in case of administration of poisons through the stomach must for the present remain conjectural. Enough is shown, however, to prove the importance of gastro-intestinal intoxication in its relation to hæmolytic anæmia.

Thus far we have considered only two of the groups of pernicious anæmia. The study of the puerperal cases is less satisfactory. No definite organic lesions have as yet been determined in these, and as a discussion of their nature could only be theoretic, they may be left out of consideration for the present. Suffice it to say that in this group, as well as in those cases in which no etiological factors of any kind are discoverable, there are the same indications of active hæmolysis in the blood, the secretions, and the organs as in the gastro-intestinal forms, and the clinical features are identical.

The rôle of hæmogenesis in pernicious anæmia, though of secondary importance and sequential, is doubtless an essential one. There must be some reason for the different effect of the same lesion in different individuals. Some persons may harbor the bothriocephalus or anchylostomum for years without the development of any unusual anæmia, just as certain persons manifest only gastric symptoms as a result of marked gastric atrophy. This difference in the state of the blood, I believe, depends more upon acquired or native deficiency in the hæmogenetic powers than in any obscure differences in the lesions themselves. This theory would furnish a ready explanation, as has been claimed by D'Espine and Picot, for the rarity of pernicious anæmia in children, in whom hæmogenesis, in common with other reparative processes, is more active than in older persons. It would harmonize with the clinical observations such as those I have cited before in the case in which pernicious anæmia was developed only after many years of gastric disorder and disease, and then ran a rapid course. Another interesting observation pointing to a natural deficiency in hæmogenesis was reported some years since by Luzet. A

girl who had been under the care of Jaccoud for chlorosis recovered entirely, but four years later, after her second confinement, came under the notice of Luzet with 781,200 red corpuscles to the cubic millimetre, and with a relative hæmoglobin value of 1.091. Doubtless, as Luzet claims, the disease was now pernicious anæmia. The previous chlorosis with subsequent pernicious anæmia are strong indications to my mind that there was here some original defect in the blood-making powers. Dr. Henry, in commenting on the above case, remarks that he had observed exactly the same conditions in one of his cases.

*Diagnosis.*—Before proceeding with the diagnosis it is important once more to set clearly before the mind the conception of pernicious anæmia which we have arrived at,—viz., that it is a form of intense oligocythæmia with a tendency to progressive deterioration, and certain definite symptoms, altogether irrespective of our ability or inability to find a distinct cause. The diagnosis, then, turns upon the character of the blood and the general symptoms, and not at all upon the absence or presence of etiological factors.

In an historical review of the study of the blood in pernicious anæmia we find a succession of observations each of which was in turn regarded as pathognomonic of the disease. One of the striking features on examination of the blood is the great irregularity in the shape of the red corpuscles,—the condition to which the terms poikilocytosis (Quincke) and schistocytosis (Ehrlich) have been applied. This was first found by Damon ("Leucocythæmia," Boston, 1864) in leukæmia, but was subsequently claimed by Quincke to be characteristic of pernicious anæmia. That this is not the case has been abundantly proved by the detection of marked poikilocytosis in cases of advanced carcinoma of the stomach, chlorosis, and other diseases. No more characteristic is the great difference in size of the red corpuscles, the existence of macrocytes and microcytes, and in particular of the small red cells of bright color and high refraction to which Eichhorst called attention in his work on pernicious anæmia, and which for a time were regarded as characteristic. All of these conditions are found in other intense anæmias, though, like poikilocytosis, less frequently and less distinctly than in pernicious anæmia. Another feature which has been falsely interpreted as pathognomonic is the mobile or amœboid character sometimes seen in the red corpuscles, but which has also been found in other diseases. The nearest approach to a characteristic condition is the rela-

tive excess of hæmoglobin, to which Hayem and Laache called particular attention. According to these authors and others after them, the blood of pernicious anæmia shows great reduction in the number of the red corpuscles without an equal decrease of hæmoglobin; so that the individual corpuscle is too rich in coloring-matter, though, of course, the actual decrease of hæmoglobin is very considerable. The presence of these conditions is doubtless practically diagnostic, but unfortunately we do not always find a relative richness in hæmoglobin. In four out of five cases of undoubted pernicious anæmia in which I have recently examined the blood, the reverse was the case, though the reduction of hæmoglobin was never much in excess of that of the number of corpuscles. The same observation was made in cases reported by Brakenridge, Dehio, Demme, and others. In all cases of genuine pernicious anæmia, however, the reduction in number of the red corpuscles is very considerable,—usually below 1,500,000. In two cases which I have recently examined, the examination of the blood showed 900,000 (eighteen per cent.) red corpuscles with ten per cent. of hæmoglobin, and 800,000 (sixteen per cent.) with thirty-five per cent. of hæmoglobin respectively. As a contrast to these figures I may cite the average result of the blood-examination in one hundred consecutive cases of gastric, intestinal, cardiac, nervous, pulmonary, and intestinal diseases, in which a certain degree of pallor led to examination of the blood. The average number of red corpuscles was 4,430,000 (88.6 per cent.), the average worth of hæmoglobin seventy-four per cent. The average of the five most anæmic of these cases was 3,820,000 (76.4 per cent.) red blood-corpuscles with 49.4 per cent. of hæmoglobin. In cases of gastric cancer the degree of anæmia, judging by the pallor of the skin, is often quite as marked as in bad cases of pernicious anæmia, but in three advanced cases I found the average result 2,890,000 (57.8 per cent.) red blood-corpuscles and thirty-one per cent. of hæmoglobin. In the four most decided cases of anæmia due to cardiac and arterial disease I have examined, the average was 4,210,000 (84.2 per cent.) of red corpuscles and forty-seven per cent. of hæmoglobin. In no case of the whole series were the red corpuscles reduced below 2,300,000, or forty-six per cent., and in none was there relative excess of hæmoglobin. The contrast between these figures and those given for pernicious anæmia is so striking as to need no further comment. Finally, Ehrlich has insisted upon the diagnostic significance of large red corpuscles contain-

ing nuclei, structures for which he proposes the name megaloblasts. These corpuscles, however, are not invariably present in pernicious anæmia, and they have been observed in other diseases attended with severe anæmia. I have seen them well marked in a case of purpura with large hemorrhages.

It is clear, therefore, that no one of the characters cited is pathognomonic standing by itself. On the other hand, a combination of all of them would make the diagnosis practically certain. In particular, I would urge that too much importance has been attached by physicians to poikilocytosis, one of the least important of the abnormalities named. What characters, then, can we regard as significant? My own observation leads me to regard as pernicious anæmia any case presenting suspicious clinical features in which the red corpuscles number less than 1,500,000 per cubic millimetre, and in which the hæmoglobin shows about the same proportionate reduction. The diagnosis becomes certain in cases in which the hæmoglobin is relatively in excess, and in which great alteration in the size and shape of the red corpuscles and the presence of large nucleated red corpuscles are observed. In addition to these characters of the blood, pernicious anæmia presents a train of clinical manifestations scarcely to be mistaken when present in their typical form. These symptoms have been so well described in the paragraph quoted from Addison that nothing further need be said on this head.

*Differential Diagnosis.*—Pernicious anæmia must be distinguished from cases of secondary anæmia, so called, especially from gastric cancer, and from chlorosis. In certain cases the striking symptoms from first to last refer to the heart or the nervous system, and may draw the attention away from the real disease.

The anæmia following hemorrhage is often intense, and the patient's face may have a deathly pallor; rarely, however, or never, in my experience, does it show the lemon color so frequently seen in pernicious anæmia. There is absence of the marked gastric symptoms and generally of the fever. It must be confessed that this last symptom is sometimes present in the anæmia of large hemorrhage, but it is exceptional. The history of the case leaves little doubt, pernicious anæmia rarely coming on abruptly. In any case, however, whether the anæmia had an acute onset after a large hemorrhage or a gradual development from repeated small hemorrhages, as in ulcer of the stomach, uterine or rectal hemorrhages, the character of the blood is sufficiently different

to make a positive diagnosis. In acute post-hemorrhagic anæmia the blood rarely shows less than 2,500,000 corpuscles and the hæmoglobin is rarely below forty per cent., death resulting in cases where greater loss of blood has been sustained. In cases of repeated bleeding the blood-count may be lower, but the hæmoglobin in these cases is nearly always disproportionately diminished. Blood-counts below 1,000,000 are exceedingly rare in such cases, as they are very common in pernicious anæmia.

The similarity in their clinical manifestations of some cases of gastric cancer to pernicious anæmia has often been remarked. The differential diagnosis is especially difficult in cases where the cancer is small and occupies the posterior wall of the stomach. In these the absence of a palpable tumor and of rapid emaciation makes the diagnosis often uncertain, as in the following case.

CASE I.—Mr. X., aged about sixty-three, had been ill for some time, complaining of gastric distress after eating, great weakness, and progressively increasing pallor. He never vomited, except occasionally after some distinct dietary indiscretion, and at such times the vomited matter presented no characteristic features. The patient came under my observation some months after his illness grew severe enough to prevent his continuing at his usual occupations. He was then decidedly pallid, the color being waxy,—neither the sallow hue of cancerous cachexia nor the lemon yellow of pernicious anæmia. He was somewhat, but not greatly, emaciated. The symptoms had grown decided, but no new ones developed. There were occasional elevations of the temperature to 99.5° or 100.5° F. in the evening. Physical examination revealed no thickening or induration in the region of the stomach. The stomach was not at all dilated. There was no pain at the stomach,—at most, discomfort after food. The examination of the blood showed 3,200,000 red blood-corpuscles and forty per cent. of hæmoglobin. The disease continued without much change of symptoms, but after four months a decided induration could be detected in the epigastrium, and after death, which soon followed, a small tabular, scirrhous carcinoma was found in the posterior wall of the stomach, near the pylorus, but not obstructing it. The stomach was not dilated.

The diagnosis in cases of this description is manifestly very difficult, and it will be seen how great a service was rendered by the blood-examination. The presence of a cer-

tain degree of emaciation was really the only point of service in the diagnosis, and this cannot be regarded as of great significance, as will be seen in the next case; neither was the absence of the lemon hue of the skin a certain indication. It may be fairly urged that the examination of the blood alone could be relied upon in instances of this kind.

A second case may be cited in which the symptoms of pernicious anæmia resembled those of cancer of the stomach. This case occurred in the practice of Dr. John Boger, with whom I saw it.

CASE II.—Mrs. X. Y., aged forty-seven years, ceased to menstruate three years previously. Her illness began apparently a year and ten months previous to her death and continued, with a single break of three months, progressively until her death. From the first she complained of marked gastric disturbances, especially vomiting. The matters ejected were reported to have been dark-colored, sometimes like coffee-grounds and at other times greenish, but there was never distinct blood. Dr. Boger never saw it otherwise than as yellowish or greenish liquid containing much mucus. The amount of vomiting was remarkable, often being repeated fifteen times during the day, and the average number being five times daily. The patient grew very weak, complained that she felt as if her heart was not beating, but did not have much actual dyspnoea or palpitation. She was habitually constipated. She is reported to have lost a great deal in weight (sixty pounds), but when I saw her a few weeks before her death she was not apparently emaciated; on the contrary, I noted the persistence of considerable subcutaneous fat, and the face was distinctly fleshy. The color of the skin and conjunctivæ was lemon yellow, the patient was weakened to the last degree, and the heart was extremely feeble, the sounds being muffled and toneless; a systolic murmur could be detected at the base and in the cervical vessels. The urine which was shown me was light in specific gravity, but darker than normal. The examination of the blood showed 800,000 red blood-corpuscles and thirty-five per cent. of hæmoglobin. Physical examination of the abdomen discovered a degree of resistance in the epigastrium, with some tenderness, but no definite tumor. The stomach was not at all dilated. She died soon after, but autopsy was not obtained.

In this case the onset of the disease, the persistence of marked gastric symptoms, and the rather characteristic vomiting warranted the suspicion of cancer of the stomach, and yet

in the later stages the appearance of the patient was enough to dispose of this diagnosis. The flabby fat with the lemon hue of the patient in themselves were strong points, for never, in an experience embracing quite a large number of cases of gastric cancer, have I seen the fat anything near so well preserved, and the yellowness of the skin in this case was very unlike the color we see in cancer, even when the liver is involved. With the examination of the blood the diagnosis was certainly unquestionable. Examination of the stomach contents could have given no reliable information, for free hydrochloric acid is frequently absent in pernicious anæmia, and the constant presence of this sign, even in cancer of the stomach, may be doubted. The slight induration in the epigastrium may have been due to a variety of causes, such as thickening of the walls of the stomach by interstitial gastritis, old gastric ulcer, and the like. It was not sufficient to constitute any evidence at all in favor of cancer, and probably was similar in nature to that found in a case of Dr. William Pepper's which I had the opportunity to examine recently during life and post mortem. In this instance the symptoms were almost identical with those in the case detailed, excepting that the vomiting was less pronounced and the vomita never brown in color. The blood-examination showed 300,000 red corpuscles and ten per cent. of hæmoglobin. There was the same induration in the epigastrium, and this was found, post mortem, to be due to thickening of the walls of the stomach near the pylorus, probably in some measure the result of an old healed ulcer, but largely to a diffuse cirrhosis.

The history of these cases illustrates rather well the points by which the two conditions—cancer of the stomach and pernicious anæmia—are to be distinguished, but one or two have not been alluded to. Not infrequently in the latter affection patients complain of discomfort or even considerable distress at the stomach, but rarely of the severe pain of carcinoma; and a tumor cannot, of course, be detected. In cases, however, where these distinct signs are absent, I should place most reliance on the presence of marked emaciation, of an ashy or sallow hue of the skin in place of a yellow tinge, and on the evidence of dilatation of the stomach. The character of the vomited matters and the presence or absence of free hydrochloric acid give us little assistance. Evening rises of temperature are more common in pernicious anæmia, but may occur in either. Finally, the examination of the blood is of signal importance. Rarely in carcinoma do

the corpuscles fall below 2,000,000, and the hæmoglobin is disproportionately reduced.

Chlorosis and pernicious anæmia would, at first sight, appear easily distinguishable, as, indeed, they are in most cases. There are some instances, however, of inveterate chlorosis in which the blood becomes progressively poorer and which eventually resemble pernicious anæmia very closely. This difficulty would be most marked in cases of *chlorosis tarda* or chlorosis in later life. Ordinarily, the great reduction in hæmoglobin with little diminution in the number of red corpuscles, together with the absence of marked poikilocytosis and of macrocytes, microcytes, and nucleated red corpuscles, render chlorosis easily recognizable. It is a mistake, however, to believe that the number of red corpuscles is never much reduced, as two recent cases of my own would prove. In one the examination showed 2,700,000 red blood-corpuscles with thirty per cent. of hæmoglobin; in the other, 2,270,000 red corpuscles and twenty-two per cent. of hæmoglobin. Even lower counts than this have been recorded. The age of the patient, the sex, the prominence of menstrual disturbances in many cases, and the absence, as a rule, of fever, usually give material aid in the diagnosis. In any case, however, in which the blood-count falls below our standard for pernicious anæmia (1,500,000 red corpuscles per cubic millimetre), and in which the reduction of hæmoglobin ceases to exceed that of the corpuscles, a transformation into pernicious anæmia might properly be suspected.

Reference has been made to the prominence of nervous symptoms in certain cases. This has been suggested prominently by the observation by Lichtheim, and after him by Minnich, Burr, and others, of organic changes in the spinal cord in this disease. The changes noted have been, in the earlier stages, small areas of hemorrhage or extravasation of blood, similar to those seen in the retina and in the serous surfaces, and in the later stages of system degenerations, especially in the posterior columns. The latter changes are probably in no way connected with the small hemorrhages. Unfortunately for diagnosis, these changes occur in other anæmic diseases, and the resulting symptoms are, therefore, of no value in diagnosis. In three cases I have examined, there was complete absence of the knee-jerk, and in two of them other symptoms which drew attention prominently to the nervous system.

CASE III.—Mr. O. B., a shoemaker, aged fifty-five years, came under observation complaining of progressive weakness and pallor and

of gastric disturbances. His illness commenced three months or more previous to my first visit, and made steady progress. The patient's habits were good, he had never contracted syphilis, and had never been seriously ill. He complained of pain in the region of the stomach, especially after eating, and occasionally he vomited. I was at once struck by the man's general appearance and by his gait. He walked rather slowly, with the legs far apart, and brought his foot down upon the ground flatly, as in locomotor ataxia. Sensation was somewhat slow in certain areas about the soles and the dorsum of the foot. The knee-jerks were entirely wanting and station was uncertain. There was no pain excepting in the stomach after food. The pupils responded normally in accommodation and to light. His face wore an habitual heavy, melancholy expression very like that in paralysis agitans, and, indeed, there was frequently a tremor in either thumb and forefinger, as in that disease. His mind was sluggish, and he could be aroused to interest in matters about him only with great difficulty. He was rather fleshy, the tissues being soft and flabby. His color was dead white, though for short periods it would assume a somewhat yellow appearance. The earlier examinations of the blood were unfortunately lost, but after some improvement in color and decided improvement in his general symptoms had taken place, the examination showed 2,000,000 red corpuscles and thirty per cent. of hæmoglobin. The patient first came under observation in May. In August he had retention of urine and had to be catheterized; subsequently cystitis developed. In spite of this, however, he improved slowly and presented a quite healthy appearance, and was free of the gastric symptoms the following winter. In the spring of the following year he again became anæmic, and afterwards passed from my observation.

In the second case there was loss of knee-jerks, somewhat ataxic gait, impaired station, and areas of diminished sensation in the skin of the feet and legs.

There may thus be marked nervous symptoms, due, no doubt, to changes in the spinal cord, but these symptoms never dominate the disease, and would not, therefore, obscure the diagnosis. In like manner, cardiac weakness, palpitations, or dyspnoea may be prominent symptoms, but their connection with the anæmic state is rarely doubtful.

*Treatment.*—The tendency of pernicious anæmia to a fatal issue must not lead to any laxity in treatment, for it is well known that temporary improvement may often be brought

about, lasting a few months or even years, and permanent cure seems to have been attained in some cases.

Byron Bramwell rendered a great service to medicine in calling attention to the value of arsenic in this disease. Sometimes the rapidity of the improvement following the use of this drug stamps it as almost a specific; in other cases, however, it seems entirely powerless. It is best given in the form of Fowler's solution, beginning with 2-drop doses and rapidly increasing to 10 drops, then more slowly to 15 or more. The remedy should always be given after meals. Frequently I have hesitated to administer it on account of gastric disturbances; but I have more often found in these instances that the gastric symptoms subsided after the drug was given than the reverse, and this has been the experience of others. It is true, however, that the stomach sometimes will not tolerate Fowler's solution or pills of arsenous acid. In urgent cases it may then be used hypodermically, but generally proves somewhat irritating. Under no circumstances should arsenic be pushed so far as to produce diarrhoea or other gastro-intestinal symptoms, as the loss of ground from an attack of diarrhoea may more than counterbalance the gain secured by weeks of judicious treatment. The tolerance of the drug is sometimes remarkable, but there is little need of increasing the dose beyond 15 drops, even when it is well borne. The value of arsenic in pernicious anæmia has been a little too well recognized, for it has at times led to a neglect of other measures almost as essential.

The patient should always at first be confined to bed, and should be required to use the bed-pan and urinal. The diet should be nutritious and easily assimilable. Meats should not be given too freely, on account of the diminished secretion of hydrochloric acid; nor, on the other hand, should sugars or starchy food be allowed in large quantity, from their tendency to fermentation. Symptomatic treatment is generally required to aid digestion and to allay gastric irritation. For the former purpose hydrochloric acid is often essential, and should always be tried where gastric fulness and fermentation are complained of. Where vomiting is severe I have found that small doses of bismuth subnitrate (5 grains) with cocaine ( $\frac{1}{10}$  to  $\frac{1}{12}$  grain) act more happily than any other remedies; and it has seemed to me that arsenic could be administered more freely and continuously with than without these adjuvants. They are best administered some time before the meal.

Our knowledge of the pathology of the dis-

case would indicate that measures should be taken to prevent putrefactive changes in the stomach and intestines and to minimize the absorption of poisons from this source. In the remarkable case of Sandoz the good effects of lavage of the stomach were most apparent, and Kaufmann and others report similar results.

Aside from the question of its influence on the disease itself, lavage may prove of great advantage in controlling obstinate vomiting and in improving the digestive power. There will generally be some difficulty at first, but after the patient has grown somewhat accustomed to the tube the stomach may be flushed every few days with little disturbance. In cases where gastric atony seems prominent and the patient's appetite is poor, bitters may be given with advantage before meals.

Intestinal lavage has been less frequently practised, and has not as yet yielded definite results. If, as has been claimed, the small intestines may be flushed out by high injections, there is reason to hope for some advantage from this method of treatment, and in the later stages of the disease it would be of additional service in supplying a certain amount of fluid to the empty vessels. The use of intestinal antiseptics, such as salol, naphthol, and carbolic acid, has been highly lauded, but the results are thus far uncertain. Free use of purgatives is distinctly less advisable than in chlorosis, excepting in the cases of parasitic pernicious anæmia. There is always the danger of deranging the stomach and of adding to the weakness of the patient. Enemata or suppositories will generally be sufficient for the purpose of securing action of the bowels, and beyond this we should not attempt to go.

Sooner or later in pernicious anæmia there comes a time when the deterioration of the blood, for which the excellent term *cachæmia* has been suggested, reaches such a grade that remedies seem altogether powerless. In this stage I have felt that the patient suffers quite as much, if not more, from the decreased quantity of the blood in circulation or from its inability to circulate freely. At this stage measures directed to assist the circulation are even more essential than arsenic. Of these measures not the least powerful is systematic massage. The interesting investigations of John K. Mitchell have shown very pointedly the effect of massage in putting larger masses of blood into circulation, and in pernicious anæmia less than in any other condition can the system spare any portion of the blood to rest idly in the tissues. A still more advanced case would call for injections of water or of blood. The safest and perhaps

the best method would be the hypodermic injection of normal salt solution in large quantities (two pints to two quarts). The intestinal flushings of which I spoke before might be of assistance here, but they could hardly prove as satisfactory as hypodermoclysis. The transfusion of blood itself has been practised by a number of investigators, and some, as Brakenridge, report remarkable improvement following the operations. It is doubtful, however, if blood-serum or blood has any great advantage over salt water, and certainly the danger of fibrin-ferment intoxication and other accidents would deter us. The administration of dried blood by the rectum possesses no special advantages.

In cases of pernicious anæmia in which improvement is seen to be taking place the treatment should be continued with great care. Under no circumstances should the hygienic and dietary regulations be relaxed or the use of arsenic discontinued. As in chlorosis relapses are frequently due to the neglect of the use of iron as soon as the patient's color is normal, so in pernicious anæmia I believe the intervals between recurrences could be materially lengthened, and perhaps permanent cure more frequently attained, by the unbroken administration of arsenic. During convalescence also I have found iron to be a valuable adjunct to arsenic. In the earlier stages of the disease, however, it is not only of no value, but often disagrees decidedly.

One word in conclusion. It seems to me that the best classification of the anæmias should assign to pernicious anæmia all cases in which the deterioration of the blood has reached the point I have indicated, whether a cause be found or not. This seems reasonable, because we have in all forms of severe anæmia presenting the features of pernicious anæmia the same evidences of great hæmolysis and defective hæmogenesis, and clinically the same tendency to further deterioration of the blood, whether the anæmia is secondary to gastrointestinal disease, to pregnancy and parturition, or apparently quite causeless. In the last group of cases no doubt similar causes will some day be found. According to this view, we look upon pernicious anæmia as a symptomatic condition, a high degree of *cachæmia*, which experience shows is a condition of great gravity, and which tends to grow worse. We are thus constrained to consider the diagnosis incomplete until the cause of this *cachæmia* is discovered, and the treatment requires attention to the underlying causes as much as to the blood itself.

## AN ADDRESS ON APPENDICITIS.

DELIVERED BEFORE THE SURGICAL SECTION OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

BY J. WILLIAM WHITE,

Professor of Clinical Surgery, University of Pennsylvania.

IT has been my intention in preparing this paper merely to review some of those important points relating to the cause, course, and diagnosis of appendicitis, and more especially to its treatment, about which great differences of opinion still exist in the profession, and to make my own slight contribution towards the acquirement of a fulness and certainty of knowledge which will permit us at some future day to lay down certain broad general propositions accepted and endorsed by both surgeons and physicians. The divergence in the views at present advanced is extraordinary. If the disease were a rare one, met with by but a few consultants and requiring special technical skill for its investigation, the reason for this want of agreement would seem evident. That we do not know to-day whether purpura hemorrhagica is a disease of the blood or blood-vessels or of the nervous system is not strange. Few of us have seen fatal cases, still fewer have had an opportunity to make autopsies or blood examinations in such cases. But there is scarcely a practitioner of five years' standing in any part of the world who has not seen and treated inflammation of the vermiform appendix, and the sum total of professional experience is already so enormous that one would think it amply sufficient to resolve all doubts and to place the guiding principles of diagnosis and treatment upon a firm scientific basis.

On the contrary, it is scarcely an exaggeration to say that attentive perusal of the voluminous literature of the last ten years, beginning with the papers of Treves and of Fitz and ending with those now in process of publication, will demonstrate that there has been made scarcely one single statement as to the essential etiology, the pathognomonic symptoms, or the appropriate treatment which has not been flatly, often violently, contradicted.

This condition of affairs reflects but little credit on the profession, and certainly renders it proper that at short intervals we should pause, review and weigh the existing evidence, and strive for the common ground of agreement which is sure to be reached sooner or later.

I shall consider only the broader questions involved, selecting those about which there are unavoidable uncertainty and anxiety and

equally unavoidable differences of opinion at the bedside. I shall illustrate clinically only from my own experience.

The valuable papers of Fowler, Richardson, and Treves are still so recent and so exhaustive that my chief function must be to present for your criticism the conclusions at which I have myself arrived, and my reasons therefor.

As regards etiology, we may first consider (a) the *predisposing* causes. The explanation of the great frequency with which the appendix becomes the seat of inflammatory and destructive lesions as compared with the other portions of the digestive tract is undoubtedly to be found in its embryology and in its anatomical relations. There can be no question that those structures which remain to us as functionless vestiges of parts once useful in our prehistoric ancestors are possessed of low vitality and but feeble resistant powers. This is as true in the life of the race as in that of the individual. It doubtless explains in part the special susceptibility of the appendix to inflammation, as it does that of the uterus and the female breast to cancer during the post-sexual period of life.

In addition, its dependent position, its communication by an orifice, often more or less narrowed, with that portion of the intestine in which inspissation of intestinal contents first occurs, while at the same time it is removed from the direct fæcal current, all appear to be conditions so markedly predisposing to inflammatory attacks that we need look no further for a sufficient explanation of the extraordinary frequency of appendix trouble.

(b) *Exciting Causes*.—Putting aside the comparatively rare cases in which tubercular or other general disease localizes itself in the appendix, we have two chief classes of exciting agencies, clinical differentiation of which is to be earnestly aimed at: the *mechanical* and the *bacterial* or *infective*. The latter comes into play usually, perhaps almost constantly, as a sequel of the former, which may, I believe, exert its action alone from first to last in a given instance, and does so in many cases.

The following anatomical points must be remembered. The appendix is commonly found curved upon itself, because its mesentery, derived from the inferior layer of the mesentery of the ileum, is too short for it. In the foetal type of the cæcum and appendix the latter has a mesentery which runs to its tip, but in the majority of adults it ends about the centre of the appendix or at the junction of its middle and distal thirds. Along the free concave border of the mesentery runs a single vessel, a

branch of the ileo-colic, and from this branch the appendix, as a rule, derives almost its entire blood-supply. Another peritoneal fold runs from that part of the ileum most remote from its mesenteric attachment and is united with the mesentery of the appendix. It carries no blood-vessels. It is the remains of the *true* mesentery of the appendix (Treves). It is interesting to note the fact that in the different types of cæcum found in our species, those which involve a disproportionate growth of the cæcum show that it derives its peritoneal covering partly at the expense of the mesentery of the appendix, which becomes more and more scanty and more vertical in direction the larger the relative size of the cæcum.

We here have the factors which enter into the production of a large number of cases of appendicitis. Distention of the ileum with gas, or of the caput coli with gas or fæcal matter, will cause dragging on one or the other of these folds, already too scanty, increase the torsion of the appendix, interfere with the blood-supply through its single vessel, and, according to the degree of torsion, produce congestion and tumefaction, catarrhal inflammation, ulceration or gangrene, with the clinical symptoms that belong to each. The anatomical conditions are so simple and easily understood, and explain so completely various well-known types of the disease, that it seems to me we may assume them to be sufficient in many cases to account for all the symptoms.

The importance of the matter will be apparent if we remember that it has been asserted that all cases of appendicitis are infectious in their nature, and that from this assumption has followed the corollary that all cases should be operated on, as one attack would mean almost certainly another at some future time.

It seems probable, though hardly yet proved, that the *bacterial* cause of appendicitis is, as a rule, the bacterium coli commune, perhaps the most interesting micro-organism that is being studied at the present day. It is almost invariably to be found in the intestinal tract, and seems in the presence of sound mucous membrane to have little or no power for evil; but it is equally well demonstrated that if the epithelium is once destroyed it has both pathological and pyogenic properties.

Experiments have shown that even a moderate degree of constriction of the intestinal canal may be followed by the penetration of its wall by this bacterium, and also that its virulence is much increased by the presence of irritative conditions such as exist in advanced constipa-

tion or marked diarrhœa, even when produced experimentally by opium or by tartar emetic.

Other micro-organisms are exceptionally associated with acute appendicitis, but the most reliable observations seem to show that in eighty-two per cent. of infective cases this bacterium is the active agent (Tavel and Lanz).

A third class of causes which may be regarded as both predisposing and exciting must be made to include fæcal concretions and foreign bodies. The latter, once thought to be the chief factors in producing the disease, are now known to be of great rarity, occurring in only about four per cent. of operative cases (Matterstock, Fowler). Fæcal concretions are found in fifteen to twenty per cent. of such cases, and there is evidence to show that they may occasionally, by their presence, give rise to the lesion of the mucous coat which precedes infective processes; but they are so often absent in cases of all grades of severity, and so often present in autopsies on persons who have died from other diseases, that they should not be considered of primary importance.

The effect of age must be taken into account in summing up the etiological factors. It is certain that the two extremes of life are notably exempt, but the explanation of this fact is thus far purely theoretical.

It is asserted that in very early life the funnel-shaped appendix, apex downward, offers fewer opportunities for the formation and retention of masses of inspissated fæces, while in old age atrophy of the mucous membrane about the cæcal orifice of the tube again widens it; but we lack positive knowledge upon these points. The very existence of the fold of mucous membrane known as the valve of Gerlach is disputed, and in any event it is so imperfect mechanically as to be presumably of slight importance.

The disproportion between the sexes requires explanation. If we accept the usual description of the anatomy of the parts concerned, there seems to be no good reason why appendicitis should be found in males four or five times more frequently than in females; but if future observation confirm the assertion of Clado, that a fold of peritoneum passes from the right ovary to the meso-appendix—the appendiculo-ovarian ligament,—and if this fold carries a blood-vessel, an obvious, and it seems to me a sufficient, explanation has been found. It has been shown (Bryant) that the male appendix is four-tenths of an inch longer than that of the female; that its calibre is slightly larger; and, possibly as a result of the latter fact, that it

contains faecal concretions in a larger percentage of cases. But these circumstances do not seem to throw much light on the subject.

The manner in which constipation, or diarrhoea and digestive disturbances generally, favor the development of appendicitis is now evident. We have a vestigial structure of relatively poor vitality and low resistant power, so situated mechanically that its one source of blood-supply is greatly interfered with by twisting or dragging, and connected by short and scanty folds of serous membrane with portions of the digestive tract especially liable to changes of form and size which thus easily produce such torsion or tension. Furthermore, a micro-organism capable of great virulence if epithelial exfoliation occurs or if any area of lessened resistance exists is almost constantly present.

*Clinical Classification.*—Thus far, while there are minor differences of opinion, we are in the main on safe ground; but when we come to take the next step the lack of definite knowledge becomes painfully apparent, and we must, as it were, feel our way with caution.

How are we to recognize clinically the cases in which the mechanical element alone is the factor and the circulatory disturbance stops short of the production of necrotic lesions of epithelium, mucous membrane, or appendix wall?

If the views advanced as to etiology are sound, not only do such cases occur, but they probably outnumber the more serious forms of the disease, frequent as are the latter. Statistics support this view, as there is good reason to believe that from sixty per cent. to eighty per cent. of cases of appendicitis recover without operation, and in the majority of these an infectious element must almost certainly be absent. Nor do the facts bear out the assertion so often made recently, that such recoveries are merely apparent or temporary. Every medical man who has had a large practice for the past decade—*i.e.*, since the knowledge of this disease has become so wide-spread (thanks to the labors of Treves, Fitz, Bull, McBurney, Weir, and others)—could disprove this statement from his own experience, unless a period of freedom of from five to ten years is not sufficient to establish permanency of cure. The all-important question to be settled at the present day is how to recognize such cases at the bedside.

If we review the early symptoms of a typical case of so-called mild or catarrhal appendicitis, and assign each to its anatomical or pathological cause, it is discouraging to find that thus far we have at this stage practically no means

of distinguishing the cases which are going to stop short of grave organic lesion from those which, unless cut short by surgery, are predestined to almost certain fatality; and yet the review of such symptoms cannot be regarded as valueless, as only in this way, as time goes on, can we hope to reach diagnostic accuracy.

Let us suppose that we have a case in which constipation (which has been obviously or unsuspectedly present in ninety per cent. of my cases) or diarrhoea, or at least some digestive derangement, has caused intestinal distention with faecal matter or with gas, or irregular and excessive peristalsis in the ileo-caecal region. The meso-appendix is dragged upon, the torsion of the appendix increased, the return of blood interfered with; the arterial supply, more difficult to disturb than the venous current, is but little affected. If we could see such an appendix we would undoubtedly find swelling and congestion, hypersecretion, nerve irritation. It seems to me theoretically unreasonable to suppose that in every such case there is necrosis even of epithelium or infection even of low grade. It is probable, however, that there is, even in the mildest cases, an exudate under pressure into the submucous and muscular coats of the appendix wall and a slight adhesive peritonitis of very moderate extent. The post-mortem findings, which show that in one person out of every three there has been some pathological condition present in the appendix, are so out of proportion to the clinical percentage of frequency, large as that is, that it seems evident that some such minor attacks *must* take place, and often with phenomena so slight that they scarcely attract attention.

The usual symptoms of such a case as we are considering, with their explanation, are: *pain*, at first general and diffused over the abdomen, because the superior mesenteric plexus of the sympathetic, which supplies the appendix, also largely supplies the intestines, and because irritative nerve pain is apt to be referred to the peripheral extremities of nerves; next and within a very short time felt in the umbilical region, because as such pain increases in intensity it is often referred to the nearest nerve centre, and the great sympathetic ganglia of the abdomen are situated in that region.

The pain at this time is often colicky in nature, and a discussion has arisen as to whether or not the circular muscular fibres in the appendix are of sufficient strength to cause it. The question will probably be settled in the affirmative, as the appendix has actually been observed in alternate spasm and relaxation when exposed in a wound (Morris); but it

seems to me unimportant, as appendix irritation may result in colicky spasm of neighboring portions of either small or large intestine.

After a few hours the pain is felt in the right iliac fossa, because it has then become a neuritis of sufficient grade to cause *tenderness on pressure*. It is a *localized* tenderness in all the varieties of appendicitis, because while the appendix itself is movable, it always arises from the same part of the cæcum, and the mobility of the latter is much more restricted. The point of pain on pressure known as McBurney's point indicates, therefore, with moderate accuracy the base, not the tip, of the appendix, and is rarely absent even in gangrenous cases, because that portion of the appendix is usually the last to be affected by interference with the blood-supply.

*Vomiting* commonly follows, has little relation to gastric conditions, and is ordinarily reflex and due to reversed peristalsis, as the ejecta show a degree of digestive change corresponding to the time which has elapsed since the last meal.

*Moderate fever* (99.5° to 101° F.) and slightly *increased pulse-rate* (90 to 110) are usually present, and are doubtless due to the same sort of absorption of intestinal products as gives rise to the same symptoms in constipation or in true bilious colic, for which cases of this kind are sometimes mistaken.

There is slight *rigidity of the right rectus muscle*, and later of the other abdominal muscles over the right iliac fossa, often, but perhaps not necessarily, due to peritonitis, and in any event arising from the fact that those muscles receive their nerve-supply from the seven lower intercostals, while the superior mesenteric plexus gets its contribution from the spinal system through the splanchnics, derived from the same seven intercostals.

This group of symptoms includes all that are of any value in this type of appendix trouble. It has been asserted (Rushmore, Osler, and others) that to speak of the first day that the patient complains of pain as the first day of the disease is fallacious, and it is said that what we recognize in appendicitis is peritonitis, which has been preceded by ulceration of the mucous membrane and a perforation of the appendix itself, and that therefore the first day of pain is rather the last day than the first day of the disease.

Now, if this were demonstrably true it would, I think, oblige us to accept the rule laid down by some surgeons, that the diagnosis of appendicitis brings with it the obligation to operate. But it is demonstrably untrue. Not

only *does not* every case with the above symptoms have precedent ulceration, but there have now been enough early operations and removal of appendices at this stage to enable us to say positively that, apart from the conditions already described,—swelling, congestion, and associated vascular changes, and nerve irritation,—there are often no grave lesions of either the mucosa, the parietes of the appendix, or of its peritoneal covering.

I have dwelt upon the symptoms belonging to this class of cases because it is just here that the field of the physician and that of the surgeon is, or should be, essentially a common one. The patient naturally and properly sends for his usual medical adviser. It would, I think, be well if the latter asked for surgical help earlier and oftener than he now does. The problem with which he is confronted is as yet unsolved. While the explanation already given of the etiology and symptoms in these cases shows (1st) that they may depend upon mechanical causes, and are not necessarily infectious, and (2d) that there is no phenomenon associated with them which of itself indicates either a solution of continuity of the mucosa, infection of the appendix wall, or peritonitis, unfortunately, it must also be said that there is none which *excludes* the graver conditions. Fitz remarked eight years ago that while a simple catarrhal appendicitis exists anatomically, it is doubtful whether its clinical appreciation is possible. If he meant that its clinical differentiation from more serious conditions could not accurately be made, his remark is still true. Colicky pain, localized tenderness, slight abdominal rigidity, vomiting, moderate fever, may be the only symptoms of a case which is going on to a rapid termination by gangrene, perforation, and septic peritonitis. It must, therefore, be decided whether, taking a large number of such cases, medical treatment or operation offers the best chance for recovery; and in reaching this decision it is impossible to ignore the oft-repeated assertion already alluded to, that all cases are essentially infectious, and that recovery from any particular attack is, as a rule, only apparent and temporary, not real or permanent.

This exceedingly important matter will sooner or later be settled statistically. At present the facts seem to be as follows: perhaps eighty per cent. of cases of this type recover under medical treatment. I have looked into the published figures as to this question with great care, and have gone back in my own case-books to the days when I saw a not inconsiderable number of medical cases annually. I believe that, on

the whole, they may be taken as approximately correct. We are, however, in special need of reliable *medical* statistics as to this point. Of the remaining twenty per cent., at least one-half can be saved by operation during the condition of localized abscess, which would form in probably that proportion of cases. This assertion is based upon my own experience and upon the more extensive figures of Richardson, Fowler, and others. Of the remaining ten, in which no protective adhesions would form, a certain indeterminate proportion would recover after operation done before septic peritonitis and intestinal paresis had occurred. This would leave a death-rate of, say, five to eight per cent.

If, on the other hand, every case were operated on as soon as seen, would this death-rate be increased or diminished? Here a similar need for surgical statistics exists, but is now being rapidly met. During the period when any particular operation is fighting for recognition, and is often performed in the face of much professional opposition, the history of surgery shows that, not unnaturally, the fatal cases do not find their way into print. This period, so far as appendicitis is concerned, has now about ended, but only very recently. No careful operator to-day hesitates to give his figures and results when he feels that they have become numerous enough to be of value, but they are not yet available in sufficiently large numbers in this particular class of cases. There is probably no one present who is not familiar with some unpublished cases of post-operative deaths, and although it is doubtless true that we all know of many more cases in which death has occurred for lack of operation, that fact does not affect the truth of my statement that we do not know the mortality of such an operation under those circumstances. It has been a favorite form of expression to speak of the death-rate as "practically *nil*," and to compare it with that of celiotomy for exploratory purposes, as in cases of tumors, etc.; but the argument by comparison is fallacious. Certain facts resting on abundant evidence, both clinical and experimental, have been ignored. We would often operate in the presence of a peritoneal infection the exact limits of which would be indeterminate. This must include not only the actual presence of micro-organisms, but the presence of their secondary products, which are now believed occasionally to give rise to so-called "chemical peritonitis." Operation, however skilfully conducted, means of necessity a certain amount of traumatism to the

peritoneum and an equivalent diminution of its local resistant power. Most surgeons of experience will agree with Treves, who in his recent admirable Lettsomian Lectures says, "There is no doubt that the nervous disturbance which attends any abdominal operation leads to some degree of intestinal paralysis. This paralysis, attended as it is by vaso-motor changes in the bowel-wall, is favorable to the absorption of septic matters from the intestine." It may be slight and may disappear spontaneously; but if it persists, it appears to permit of filtration through the intestinal wall of bacteria or their products. These latter are readily taken up by the peritoneum, and a septicæmia begins. It should also be remembered that Terillon has shown that the effect of irritation of the parietal peritoneum, which is chiefly disturbed in ordinary exploratory operations, is comparatively feeble, while it is violent and intense when that covering the intestines is involved (Treves).

Therefore, while both my experience and my observation lead me to believe that, in good hands, these very early operations will have an extremely low mortality, perhaps lower than that of the disease treated medically, I do *not* believe that it will be "practically *nil*," and, at any rate, I do not think it fair to our medical colleagues that we should take that position before we are able to demonstrate it.

As to the diagnosis of the class of cases we have just been considering, it is to be made chiefly from stercoral typhlitis, a condition which has been so overshadowed during the advance of our knowledge in regard to appendiceal disease that we are in danger of acting as if it were non-existent. In some elaborate reviews of the diagnosis of appendicitis it is hardly mentioned, and yet a very moderate clinical experience ought to convince any careful observer that it is not infrequent. It has many features in common with appendicitis, and it is quite possible, as has been asserted, that to some degree this is present in most cases of stercoral typhlitis, but the independent existence of the latter condition has been shown unquestionably both at autopsies and at operations, where severe forms of typhlitis and perityphlitis have been found to be dependent on stercoral ulcers of the cæcum, and the appendices were normal. It is unquestionably true that in the vast majority of cases of severe inflammation and suppuration in the right iliac fossa the appendix is at fault, but it should not be forgotten that in many of them the original trouble is a constipation, associated with distention of the cæcum by fæcal masses often

containing undigested food, and exciting both mechanical and chemical irritation. The relation of the mild attacks of appendicitis to digestive derangement has been quite unmistakable, in my experience, and it is not very uncommon to find in relapsing appendicitis that one particular article of food is the especial exciting cause of an attack. (See Case XII., page 399.)

Now, if in so many cases fecal distention of the cæcum is the starting-point of appendicitis, it is reasonable to believe that in some of them the trouble does not pass beyond the cæcum, and it is important to recognize these cases, because the prognosis is so much more favorable and operative measures need not, as a rule, be thought of.

They have occurred with me chiefly at the times of life when appendicitis is less common, and more especially in children. They can be recognized with certainty only by the initial presence of a doughy sausage-shaped tumor in the cæcal region associated with the usual symptoms of appendicitis in a modified form. The localized tenderness is not so great; the fever is very moderate; vomiting is rarely a prominent symptom; constipation is almost invariable, though occasionally a spurious diarrhoea (analogous to the "incontinence of retention" in bladder cases) may make its appearance.

The discovery of a tumor at the very beginning of an attack of apparent appendicitis of obviously mild type, would, I think, justify the diagnosis of stercoral typhlitis, but I know no other way in which the diagnosis can be made, and in the absence of that symptom it would be safer to consider doubtful conditions as almost certainly indicating appendicitis.

CASE I.\*—A little girl, whom I saw in consultation with Drs. Lewis D. Harlow and Louis Starr, had an attack of vomiting followed by umbilical pain and almost immediately by right iliac tenderness. When I first saw her, about *eight hours after the beginning of the illness, a distinct mass could be felt in the cæcal region*; tenderness at the edge of the right rectus in the omphalo-spinous line was marked; she lay on her back with the knees drawn up; her temperature was 101° F., her pulse 110. Her mother stated positively that the bowels had moved regularly and that she had never known her to be constipated. Salines, which had already been given, were continued. Hot fomenta-

tions were applied to the abdomen. The diet was reduced to teaspoonful doses of peptonized milk at hourly intervals.

At the end of twenty-four hours there was a little aggravation of all the symptoms; at the end of forty-eight hours there was slight tympany; at the end of sixty hours, when we were considering the advisability of operation, there was an enormous stool, followed by two others in rapid succession and by a complete disappearance of all the symptoms.

It will be convenient now to consider the non-operative treatment of these mild "catarrhal" cases before passing on to those of the next grade.

Certain indications are so clear that there is practically no difference of opinion about them.

Ordinary clinical experience with other forms of enteritis demonstrates the value of *absolute rest* in bed and on the back. The frequent inability of the stomach to retain food, the certain inability of a portion of the intestinal tract to take care of the residue, even if it reaches that point, and the absolute need for the avoidance of all sources of local irritation point so clearly to a diet reduced to the lowest possible terms that it is always a matter of surprise and disappointment to me to find patients, even in the early and acute stages of this disorder, being fed regularly every two, three, or four hours with portions of milk and lime-water, or often with more harmful foods, as though they were in the last stage of some exhausting disease. No one, beginning in comparative health, ever starved to death in three or four days. There is no doubt that many of these patients have been fed to death. *Starvation* in its therapeutic sense is one of the most important elements of treatment, and the nearer the patient comes to taking nothing except an occasional sip of water the safer he is.

The *local* use of *heat*, drawing the blood to the superficial veins of the abdomen, of *cold*, by means of ice kept on long enough to bring about local anæmia extending to the parietal peritoneum or deeper, or the actual abstraction of blood by *leeches*, seem to have about equal claims to employment. Personally, I prefer either the heat or the bloodletting. I strongly object to blisters, iodine, and the use of smeary ointments as rendering the skin more or less unsuitable for a satisfactory operation later, if one be required.

The question about which there is the widest apparent divergence of opinion concerns the respective merits of the use of salines and the use of opium. The very briefest review of cur-

\* Wherever possible I have italicized the special point or points which these cases are intended to illustrate.

rent literature will show that the writers on this subject have practically ranged themselves in two camps; often, however, expressing most decided opinions without specifying at all the class or classes of cases to which they refer. Avoiding the extremists and taking the calmest and most carefully considered articles as examples, we find Osler saying, "If there is much pain, opium should be given hypodermically or by the mouth. . . . I would protest most earnestly against the indiscriminate use of saline purges." Pepper says that "so far as medical treatment goes, the great stand-by is opium in full doses;" and adds, "that the same reasons that indicate opium should lead to the avoidance of salines." On the other hand, Treves says, "Give as little opium as possible;" and adds that he is quite convinced of the value of aperients in the early stages of appendix troubles and sometimes throughout the attack; while Fowler, after seeing one hundred and sixty cases, says that beyond the careful use of salines in the earliest stages of the mild cases the less medical treatment the better; but adds, "above all things the use of opium must be avoided as much as possible."

These four quotations will suffice to represent the opposing views.

My present opinions, which have not been reached without some thought and much hesitation, but which seem to me more and more satisfactory as my experience widens, are based on the following considerations:

I have never happened to see one of these extremely mild cases in which there was diarrhoea, nor one in which the bowels moved easily after enemata or aperients, run on into the graver type of case. I will doubtless meet with this some time, as others have done so, but thus far there has been no exception to the rule in my personal experience. I read that of twenty-two cases of peritonitis from appendix troubles occurring at the London Hospital there were nine cases of constipation, with four deaths, and thirteen cases in which the bowels were loose or were easily moved, with two deaths. I find upon analyzing Richardson's tables that of those acute cases which recovered without operation, constipation is mentioned as a prominent early symptom in four, diarrhoea in ten, while in those cases which died without operation there was early constipation in three and diarrhoea in one. The force of these figures is much increased if we remember that where neither diarrhoea nor constipation was mentioned, it is fair to presume that the bowels moved regularly. There was thus eight per cent. of constipation among the cases that

recovered, and twenty-eight per cent. among those that died. In addition, every surgeon who has had any abdominal work knows how essential it is to have the intestinal tract thoroughly evacuated before operation. It is in this way and by the prompt administration of salines according to Tait's plan on the first appearance of symptoms of "pseudo-ileus" that general peritonitis is often avoided, not cured, as is incorrectly stated. As any case of appendicitis may become an operative case, it is of the highest importance that in the early stages whatever remains of peristalsis should be encouraged and not destroyed by the use of opium. Furthermore, it has been shown experimentally that after an injection of a culture of the virulent colon bacillus into the peritoneum of animals, if the dose is not too large, the animal recovers after an illness of which diarrhoea is a symptom (Treves).

For these various reasons my rule in practice is: In all ordinary mild cases give salines until free purgation is assured, and then continue the action more gently by the use of divided doses of calomel, which by its antiseptic properties has a distinct value, and through its effect on the portal circulation aids also in the depletion of the ileo-colic vein and its tributaries.

Spontaneous severe colicky pain, altogether distinct from pressure tenderness, is the only indication I recognize for the use of opium, and I give it then in minute doses combined with enough calomel to overcome its constipating tendency.

I am at present satisfied that this treatment is practically sound, and I am certainly convinced that many patients to whom opium is given early and freely die partly because the imperative need for operation is thereby disguised and the favorable opportunity lost, and partly because the free evacuation of the bowels, so necessary for success, is interfered with.

I may say here, before leaving the subject of the medicinal treatment at this early stage, that in my judgment not enough attention has been paid by either physicians or surgeons to what might be called the antiseptic treatment of appendicitis. It is reasonable to suppose on *a priori* grounds that in a disease the most serious varieties of which are produced by infection with micro-organisms whose habitat is the digestive tract, intestinal antisepsis would be of distinct value. And furthermore, I would say that in all forms of sepsis present or threatened there is good reason for believing that the systematic administration of soluble and powerful antiseptics is of far more importance than

is commonly supposed. A record which I will shortly publish of observations in this direction made on cases of carbuncle and of chronic furunculosis will, I think, be convincing of the possibility of powerfully influencing through the blood the susceptibility of the entire organism to bacterial infection and growth. But I merely mention the matter to-night to bring it to the attention of the medical men present, and to ask for their views and experience in this direction.

If the medicinal and dietetic treatment has been successful the symptoms gradually disappear, the local tenderness often being the last to go. Scrupulous continuance of rest, restricted diet, and mild laxatives should be continued for from one to two weeks.

If the symptoms are worse instead of better at the end of forty-eight hours, or earlier than that if there is *severe, sharp* pain, increased tenderness and rigidity of the abdomen, and beginning tympany, either local or general, I think there can be no doubt that surgical interference offers by far the best hopes of recovery. In the majority of cases these phenomena then indicate a perforation of the appendix wall, possibly not macroscopic, but permitting the filtration through it of bacteria and their products.

So far as diagnosis goes there is practically no condition for which such a case can be mistaken. The previous history with the symptoms above described place it beyond all peradventure. Occasionally there may be an extraordinary case in which coexistent disease of another kind would cause doubt or confusion, but I am occupied this evening not with medical or surgical curiosities, but with every-day cases, and these at this stage can scarcely be misunderstood.

We are on equally assured pathological ground. In thirteen such cases examined by Van Cott there were evidences of obstructive conditions found in the vessels of the mesentery of the appendix, either thrombus or endovasculitis, while in the appendix wall there were round-cell infiltration, necrotic areas, and purulent foci. Interstitial neuritis was also present (Fowler).

It is of course not impossible for resolution to take place in these cases. Not every one of them goes on to gangrene in mass and to infection of the general cavity. Even if resolution does not occur, a protective inflammation may wall off the appendix, and does so in a large proportion of cases.

But there is absolutely no way of recognizing with any reasonable certainty which of

these three events will follow: resolution and recovery; localized abscess, with ninety to ninety-five per cent. of chances in the patient's favor; or general peritonitis, with almost sure death if it is once well established.

If operation is done at this stage it is usually easy. An incision two or three inches in length is better than a smaller one, and is most advantageously placed if it is oblique with its centre a little outside of McBurney's point. When the belly is opened there will usually be found a moderate excess of peritoneal fluid, clear or only slightly turbid and without odor, a circumscribed peritonitis, weak adhesions between the cæcum and the parietal peritoneum and adjacent intestines, and a tense, swollen appendix, either angulated and twisted or erect and prominent, according to the length of its mesentery. It can be removed most safely by making a circular incision through its peritoneal coat, three-fourths of an inch from the base, reflecting it like a cuff, ligating the mucous coat with a circular ligature, touching its surface with a drop or two of pure carbolic acid, replacing the peritoneal coat, and stitching with a Lembert suture. When the peritoneum has become thickened and brittle, almost equally good results can be obtained and more expeditiously by throwing a ligature around the whole appendix one-quarter to one-half inch from the cæcum, removing the organ, and cauterizing the stump with carbolic acid. The appendix will show the microscopic changes I have described. It would be absurd before this audience to waste time with talk of the importance of asepsis or with remarks about the details of technique.

As a rule, the wound may be closed without drainage, and, if closed properly, the risk of ventral hernia is a very small one. The operation will certainly have a small mortality, but for reasons already given it will be a larger one than if it were a simple exploratory operation.

While, however, I believe more patients would be saved by operation at this time than by any temporizing measures, I find that that opinion when expressed at the bedside is not always coincided in by the medical attendant or the patient.

I may say, therefore, that experience has taught me to await events with more equanimity: 1. If the bowels are loose. 2. If the pain is dull and throbbing (connective-tissue pain, —Bryant), and not sharp and lancinating (serous-tissue pain); the former I refer to a tense appendix, with infiltration of the wall, but without gross perforation or intense or widespread peritonitis. 3. If the spot of greatest

tenderness on pressure by a finger-tip is not precisely at McBurney's point. This is an empirical rule; but I have noticed in a number of cases in which there was delay at this stage, and which finally did well without operation, that the point of greatest tenderness so anxiously investigated at each visit was more or less remote from the usual region. If this proves to be an observation of any value, it will be for the following reasons: the body and tip of the appendix are less vascular, and less richly supplied with nerves than the base; they are, therefore, more commonly the seat of the earliest degenerative changes. If those changes are very intense, and particularly if they go on to gangrene, sensibility in the body and tip is quickly lost, and pain at the more fixed portion of the appendix, the base, becomes the prominent symptom, and is recognized at the usual point. If the changes are of a milder type, such as permits of recovery by resolution, sensibility of the tip will be retained, and will be felt at various points on the abdominal surface, varying with the position of the appendix.

4. If vomiting is not marked. It is not usually a prominent symptom of this stage of appendicitis in cases which lead to recovery. It will almost always be found present in an inverse relation to the looseness of the bowels. Its absence is a very favorable circumstance, and always, and I believe justly, influences my prognosis. 5. And, finally, I am less anxious during this period of delay if, without marked change in the general condition, increased resistance, slight dulness, and the presence of a mass recognizable by palpation indicate that a localized abscess is forming, shut off by adhesions from the general peritoneal cavity.

CASE II.—A young man, whom I saw in consultation with Drs. John Musser and William Pepper, had the usual symptoms of a moderate attack of appendicitis for three days. At the end of that time the conditions present were: distinct rigidity of the abdominal muscles over the right iliac fossa; slight tympanitic distention of the same region; temperature,  $101.5^{\circ}$  F.; pulse, 110; *marked tenderness at a point just above Poupart's ligament at the junction of the middle and inner thirds.* He had been continuously on salines. His stomach was retentive, but there had been no bowel movement for two days. He was getting no food. I was strongly inclined to operate, but delay for twelve hours was decided upon, and at the end of that time there was such marked amelioration of all the symptoms that operation was not further considered.

We may pass in this condition of uncertainty into the period extending from the third to the fifth day with very little alteration of the symptoms, but usually during this time one of the three events already mentioned will occur. If the bowels continue to act spontaneously or with mild laxatives; if the tympany, which may be quite marked, begins to decrease; if the fever lessens, and especially if tenderness remains well localized and tends to subside, the prognosis is, on the whole, favorable, although the patient is unquestionably in grave danger during every minute of this time. If no amelioration of these symptoms occurs, although no new ones develop, the case at that period, from the third to the sixth day, becomes one of the most anxious and trying with which either physician or surgeon can be confronted. It is the time at which, as Richardson has tersely put it, we may feel that it is "too late for the early operation and too early for a safe late operation." It is probable that adhesions have formed, offering a certain degree of protection against general infection, but experience shows that in many cases they cannot be depended upon, and we may find at any visit that the tenderness and tympany have increased in intensity and become more widely diffused, that vomiting is more frequent and uncontrollable, that the fever has risen to  $104^{\circ}$  or  $105^{\circ}$  F., or, more ominous still, has disappeared, leaving the temperature subnormal; in other words, that the general peritoneum has become involved. If, with the fear of this occurrence before us, we proceed in such a case on the fourth or fifth day to removal of the appendix, we do so with the knowledge that there is much risk of breaking up the recent and delicate adhesions which have thus far been the patient's safeguard, and we know that it is not always possible under these circumstances, however thorough and minute our precautions, to prevent a spread of the infection. Here, again, I am not in sympathy with those surgeons who speak in an airy and confident way of the overwhelming advantages of operation, but am once more of the opinion of Richardson, whose excellent work and writings on appendix disease entitle him to frequent quotation, and who says that "there is no more difficult operation in surgery than that of removing an appendix at this stage without infecting the general peritoneal cavity." The question certainly is one of the most important connected with this discussion.

I have tried earnestly to find some light upon it, but my own experience and the recorded testimony of the profession have alike failed to

help me. With absolutely identical symptoms on which to base a prognosis at this stage, any two cases may go on, one to recovery, the other to death, and the same remark applies to the results of operation. On the whole, however, this very uncertainty tends to favor operation, in spite of its undoubted dangers.

We are now dealing with a case of circumscribed peritonitis threatening to become general. The infection which is giving rise to it is a progressive one. Ziegler and others have shown that the effect of injecting a culture of the colon bacillus into the peritoneum of animals varies, other things being equal, with the dose. In the mildest cases an illness in which, as has already been stated, diarrhoea is a symptom is followed by recovery. In another grade a localized purulent peritonitis is produced, running a slow course. If the dose is larger a fatal diffuse fibro-purulent peritonitis follows, and if still larger death may occur from acute sepsis before there has been time for any of the phenomena of peritonitis to develop. The peritoneum has thus undoubted ability to take care of certain quantities of bacterial poison, but succumbs to larger ones, and for this and other reasons it cannot be questioned that if choice had to lie between infection during and because of an operation on the third or fourth or fifth day, and, on the other hand, an operation to which we are forced on account of spontaneous infection at some later period, the former is by far to be preferred. Many recoveries do occur after operation at the beginning of a general peritonitis, but the difficulties and dangers of the case are both so greatly increased at that time that if its probable occurrence could be predicted with any certainty, operation in anticipation of it would with equal certainty be indicated.

Statistics as yet help us but little, because we do not know even approximately what proportion of patients in whom the policy of delay is adopted survive or perish.

The reported operative cases are of little use, as many of the operations were undertaken in the presence of septic peritonitis. Fowler, for example, in forty-nine operations, on the fourth, fifth, sixth, and seventh days, lost twenty-one of his patients; but eighteen of them had this condition pre-existing, and the length of time it had existed is not stated. On the other hand, I find from Richardson's figures that twenty-eight operations followed by death were done at a time averaging five and a half days after the first symptoms, while in fifty-eight operations followed by recovery

the average pre-operative time was nine and one-half days.

This, however, may indicate merely what might be called the survival of the fittest, and can certainly not be used as an argument in favor of delay.

It is obvious that until we have figures, especially from our medical colleagues, which will enable us to contrast the results of expectancy with, first, the mortality of operations in the presence of distinct, but presumably localized, peritonitis and before general infection, and, next, the mortality at the beginning of general infection, we cannot settle the matter statistically.

The diagnosis between appendicitis and other distinct diseases during this period presents but few difficulties. Many of the long lists of differential diagnoses already published are useless to the practitioner of ordinary intelligence, and serve only to add to the flood of pointless compilations with which we are overwhelmed.

It is the diagnosis between the existing conditions in and about the appendix in any given case, and their probable outcome, which is of the most vital interest, and on which no amount of time would be wasted if it advanced us ever so little in our bedside knowledge of these cases at this important stage. Much weight has been attached to the presence or absence of pus, and to the great desirability of finding some reliable test for its presence. Thus far all such tests are purely theoretical, and none that have had a fair trial have given satisfactory results. It is certain that at present no safe prediction as to this point can be based on the condition of the blood or the condition of the urine. The leucocytosis described by Richardson as being present in perforation has no apparent relation to suppuration, but it requires and deserves further investigation.

But, after all, while information as to the presence or absence of pus is much to be desired, what we need far more, and what would be of far greater use to us, is information as to what symptoms indicate a persistent circumscription of the inflammatory action, whether it be suppurative or otherwise, and what symptoms point to an extension to the general peritoneum. In the presence of the latter we would operate altogether irrespective of the existence or non-existence of suppuration. Treves has shown that in the larger proportion of cases of fatal peritonitis the leading symptoms are those of poisoning, and not of inflammation. Extension of the latter to the general peritoneum means that a large part of the

enormous area of that membrane (probably as great as that represented by the whole cutaneous surface) takes part in the absorption of the products of the bacterial infection.

It should not be forgotten that the cases in which suppuration is most pronounced are among the most favorable examples of peritonitis, and that the most hopeless cases are often among those that show the least inflammatory changes. For example, seventy out of one hundred cases of peritonitis at the London Hospital died. In thirteen of these the cause of the peritonitis was either cancer or tubercle or was never found. That leaves fifty-seven examples of death from peritonitis. Now, in only fifteen of these was the exudation purulent; in eleven it was described as sero-purulent; and in the remaining thirty-one cases there was not even a suggestion of pus (Treves). It is evident that we need far more than a test for pus to aid us in these cases, and that the talk which is so common about operating as soon as there is a recognizable sign of pus, while it is correct so far as it goes, is superficial, and fails to take into account problems which are both more serious and more recondite.

I shall recur to this subject for a moment later; but as to this aspect of it, must admit that at present we have no safe rule to guide us as to the greater or lesser likelihood of generalization in any particular case of appendicitis in the stage of circumscribed peritonitis. As we know clinically that localized varieties of peritonitis and circumscribed exudations are very rare in the area occupied by the small intestine, and as we know both clinically and experimentally that the peritonitis which involves its covering is of the most violent and intense variety, it might perhaps be safe to say that where the area of tenderness is small and distinctly confined to the cæcal and pericæcal area the prognosis is more favorable than when it extends beyond that region, and the latter occurrence might thus be regarded as pointing in the direction of generalization, and, therefore, of operation; but I have no reliable observations to confirm this view, which may be unsound as a practical guide. Of the phenomena which mark the actual onset of diffused peritonitis, perhaps the gradual increase of tympany and tenderness and persistent vomiting are the most significant.

If operation is done in a doubtful case at this time, it will differ from the procedure already described in the necessity for thorough cleansing of the peritoneal cavity, if it is found to be infected, and in the employment of drainage. It differs also in the great care which must be

taken, if a localized cavity containing purulent or sero-purulent fluid is found, to avoid making a communication with the general cavity of the belly. Large numbers of cases show now beyond all doubt that it is infinitely better to leave the appendix than to make a prolonged search for it, or to employ much manipulation in freeing it from adhesions preparatory to removing it. The later the time of operation and the stronger and firmer the abscess wall the safer the operative procedure becomes; but in every case and at every period, if there is a circumscribed abscess, it is poor surgery to insist upon finding and taking away the appendix in the face of obstacles.

CASE III.—I saw some years ago, in consultation with Dr. Newberry, of Fort Washington, a young man with all the phenomena of appendicular abscess. An opening over the most prominent part of the fluctuating swelling gave exit to a pint or more of fetid pus. The appendix was gangrenous quite down to the base. *but was partly embedded in the inner wall of the abscess cavity. I freed it with some difficulty* and as gently as possible, ligatured it on a level with the cæcum, and strengthened the intensely inflamed area at that point with an omental flap. I drained with a glass tube. The operation was done rapidly, there was no shock, and the patient had not a bad symptom for twenty-four hours. Then he developed general septic peritonitis and died within a day or two.

This case operated on very early in the period of appendix surgery will always be a source of regret to me. I did what was then considered the ideal operation in the face of great difficulties, but lost the patient. From that day to this I have never lost a case in which there was at the time I operated a well-localized abscess. I have often removed the appendix when it was easily found, but I have oftener left it without more of a search for it than could be made in two or three minutes.

CASE IV.—Later, I saw, in consultation with Professor William Osler, of Johns Hopkins, and Dr. Kerr, of Washington, a lady who was suffering with an attack of appendicitis of a chronic type. She had been ill for more than two weeks. There was a thick-walled tumor in the right iliac fossa. An incision through thickened and oedematous tissues gave vent to a large quantity of fetid pus. Digital exploration with the finger showed dense adhesions in every direction. *No further search for the appendix was made.* A drainage-tube and iodoform gauze were inserted and the angles of the

wound closed. Recovery was uninterrupted. A sinus which persisted for a time finally healed.

CASE V.—I operated, in consultation with Drs. Mackenzie and Sheppard, of Trenton, on Mr. P., a brewer, exceedingly stout and in an apparently profoundly septic condition. The abscess cavity which I opened was so immense that it seemed almost certain that it was practically the general cavity of the peritoneum. No free coils of intestine could be felt, however, even with the whole hand introduced and swept cautiously around the walls of the cavity, which reached over beyond the middle line. A loose faecal concretion was found. No search was made for the appendix. Irrigation, iodoform, glass drainage, and iodoform packing were used. An unfavorable prognosis was given, but the patient made a rapid and uneventful recovery.

I could record many such cases, but there is not enough variety about them to make their details of interest. They have recovered without exception.

The soundness of this procedure is abundantly certified to. In a series of cases of perforative peritonitis reported by Kaiser, of six examples in which the exact point of perforation was never found, five recovered. Treves says, "The wisdom of doing no more than is necessary, or as little as is obvious, is well illustrated in these cases. A clump of adherent intestines will often cover and protect a perforation, and the ubiquitous lymph will many times close such an opening with more speed and security than are provided by any system of suturing. As the surgeon, therefore, reaches what appears to be the starting-point of the peritonitis, he must proceed with the utmost caution, and be not only prepared, but rather inclined to leave the actual *fons et origo mali* undemonstrated. The main purpose of the operation is to allow a noxious exudation to escape and, if possible, to free the peritoneum of the cause of its trouble. In the class of cases now under discussion, a perforation will be very often the starting-point of the peritonitis; the lapse of time and the plastic character of the inflammation afford evidence that the perforation is for the time being closed. If the operator can rid the serous cavity of the effects of the perforation, he may very often leave the breach itself to be dealt with by natural means." In seventeen cases in which Fowler did not remove the appendix, and which recovered, there was recurrence in only two within the next two years. The remainder had gone

for variable periods, three of them for between three and four years, without any symptoms. I have now had fifteen such cases myself, and in none of them have I heard of any subsequent trouble other than the occasional occurrence of a small faecal fistula, which sometimes relapsed once or twice, but has thus far finally closed spontaneously and permanently in every instance.

Usually at the operation the caecum is the first structure recognizable after the abdominal wall is incised, and the anterior muscular band leading to the base of the appendix is occasionally a useful guide; but generally the increased resistance felt by the finger at a particular point, followed by inspection with the wound gently held open by retractors, will reveal the whereabouts of the organ. If it is found in this way and can easily be isolated by the finger and a thread thrown around its base, its removal is clearly indicated. If, however, as in a case operated on a few days ago, it is deeply embedded in the abscess wall and its tip only is visible, it is far better to leave it undisturbed.

CASE VI.—The patient was referred to me at the German Hospital by Professor James C. Wilson. She was a woman of fifty years of age, but had not had her menopause. She was of low intelligence, and no satisfactory history could be obtained. It was certain, however, that after her admission to the hospital she complained bitterly of pain in the left iliac region, and only later of pain and tenderness on the right side. Vaginal examination revealed a firm, resistant, tender mass on the left side and nothing abnormal on the right side. Her temperature was 101° to 103° F.; her pulse 110. There was dulness over the right flank. There was general tympany; some general tenderness, more marked, however, on the right side and at McBurney's point. Borborygmi could be heard by abdominal auscultation. The bowels moved freely under salines, after which there was a drop of two degrees in temperature and some improvement as to her feelings, but the local phenomena remained unchanged. An incision gave exit to perhaps twenty-four ounces of horribly fetid pus, which had been under great pressure. Inspection showed the distal extremity of the appendix projecting into the cavity from among a mass of intestinal coils covered with lymph and firmly matted together. No effort was made to remove it. The patient has done well.

The same reasons that forbid interference under these circumstances have prevented me from looking long or earnestly for other foci of

suppuration. Sometimes they may easily be recognized and opened into the larger abscess cavity by the finger; but when this is not the case, I think the patient's chances are better if the possibility of their presence is disregarded, as they are found in only a minority of cases, and as then they not infrequently open spontaneously into the original cavity.

Irrigation, drying the cavity, dusting it with iodoform, the insertion of a large, thick-walled, rubber drainage-tube, and light packing with iodoform gauze complete the operation, as I am in the habit of performing it.

The prognosis during all this period is in direct relation to the localization of the symptoms and to the absence of general sepsis. Nothing else is of much importance. Accordingly, a well-marked tumor, a moderate fever, a high-tension pulse not of excessive frequency, a limitation of the tenderness to the right iliac region, even if there it be exquisite, any evidence of continued peristalsis, such as the recognition of borborygmi by abdominal auscultation, are all favorable.

But at this or at any stage of this disease, from the earliest onset to the period of complete recovery, we may meet with quite a different set of symptoms. In the beginning the torsion of the appendix may be nearly or quite complete; or with moderate torsion there may be an exceptionally imperfect blood-supply; or in either case the bacteria present may be of especial virulence or in unusual quantity; or, finally, the resistant power of the individual may be markedly defective. According to the varying predominance of one or the other of these factors, we meet clinically with types of cases directly comparable with those conditions produced in animals by experimental inoculation with the colon bacillus. Two of these we have now very imperfectly considered,—the mild cases in which the peritonitis is an inconsiderable element and which usually end in recovery, and the cases of distinct circumscribed peritonitis running a more chronic course and ending either in resolution or, if more severe, in localized suppuration. Either with or without these precedent stages we may have a general septic peritonitis. If this results from spread by continuity,—the usual mode in which a localized peritonitis becomes general,—or by infection through the lymphatics of the appendix and meso-appendix, or by a slow leakage of inflammatory products through the appendix wall, or by the migration of bacteria along the same channels, its approach may be slow; if it follow the rupture of an abscess it will be much more rapid.

CASE VII.—In a case recently seen, in consultation with Dr. Joseph Martin and Dr. Thomas Yarrow, the patient had been in excellent general condition up to noon of the fourth day of his illness; temperature,  $101^{\circ}$  F. to  $102^{\circ}$  F.; pulse, 90 to 105; moderate vomiting, obstinate constipation. When Dr. Yarrow first saw him, *six hours later, the temperature had dropped to normal, the pulse was 120 and thready.* There was great restlessness; constant rejection of small mouthfuls of fluid; a distended board-like belly. When I saw him, within a few hours, the pulse was 140 and running; the temperature normal; consciousness perfect; restlessness incessant. No operation was advised. He died in a short time.

CASE VIII.—I saw, in consultation with Drs. Johnson, of Lawrenceville, and Elmer, of Trenton, Mr. B., a teacher in the Lawrenceville School, New Jersey. He had been apparently convalescing from an attack of appendicitis when, contrary to orders, he walked from one room to another. *He was at once seized with a violent abdominal pain, which was immediately followed by distention, vomiting, and symptoms of shock.* I operated a few hours later, irrigating and draining the purulent cavity, which contained a large quantity of pus, but he died the next day.

CASE IX.—An almost precisely similar case, seen at Princeton by Dr. Agnew and me, in consultation with Dr. Bergen, had a similar course and termination. In this case also operation was tried as a last resort.

But in either event it is usually of the fibropurulent variety, and is accompanied by much exudation. The patient soon presents the typical picture of diffused peritonitis: incessant restlessness, greatly-distended belly, tender everywhere to the lightest touch, dorsal decubitus, constant vomiting of small mouthfuls without much effort, thoracic respiration, obstinate constipation, absence of intestinal sounds, high fever, followed towards the end by subnormal temperature, cold sweats, and collapse.

It is of great interest, however, to note that even the cases which tend to run this course will occasionally recover when seen and operated on at the very onset of the generalized symptoms. In fact, if operation *precede* the development of septic paralysis of the intestines, a very fair percentage of such cases will recover; but after the latter phenomenon has appeared I regard the case as absolutely hopeless. If it is unmistakably present, it is, I

think, best to decline to operate, as we will have less difficulty in obtaining consent to operative interference where we can do more good, if there are fewer deaths, which, however unjustly, seem to the laity to be, so far as operation is concerned, in the relation of effect to cause.

But if there is any doubt about it, it is well to open, irrigate, and drain the abdomen. I have already called attention to the fact that the suppurative cases are among the most favorable examples of peritonitis, whether general or localized. When localized they are *very* favorable, and even in these general septic cases the more the suppurative process overshadows the toxæmia the better the patient's chances. It may be well to note a possible explanation of this fact. Reichel some years ago determined that by gradually administering increasing doses of pure cultures of pyogenic micrococci to the peritoneum of an animal an immunity against an extremely large dose of this poison could be produced.

The same immunity was acquired in the same way against the introduction of a sterile filtrate from the cultures and against the metabolic products of the staphylococci. Control experiments were uniformly fatal in animals not previously prepared.

Attention has been called by Binnie to the clinical differences between the rupture of a chronic pyosalpinx, even if of enormous size, and a case of very acute or so-called fulminating appendicitis with gangrene of even a small portion and escape of the contents.

CASE X.—I saw some time ago, in consultation with Dr. William Pepper, a child in whom, within a very few hours of the onset of the symptoms, there was *gangrene, not only of the appendix itself, but also, and apparently as a result of an overwhelming bacterial infection, of an adjacent portion of the ileum*. Distention was enormous. An enterostomy was done with a little temporary relief, but the child died soon afterwards.

The chances of the patient, if operated on in a reasonable time, are far better in the former than in the latter case. Operation within three hours of the very first symptoms of such an event has failed to save the patient. He dies, as Treves has emphasized, not of the inflammation, or still less on account of any suppurative process, but from a profound toxæmia. In the pyosalpinx there has been an opportunity for slow auto-inoculation; in the rapid gangrene of appendicitis there has been no time for this process. It is in such cases that we often find the flat, silent belly indicative of

absolute paralysis of the *whole* intestinal tract, no peristalsis remaining in any portion to force gas into any other portion; and we have all the symptoms of shock and collapse. Here also operation is useless and to be avoided.

But in the suppurative cases, for both the practical and theoretical reasons above given, if any sign of peristalsis remain—and this is the very best indication I know of as to interference or non-interference in these excessively grave cases—it is better to open and irrigate, even if the patient is liable to die on the table. Occasionally a desperate and apparently hopeless case will be saved.

Possibly the protective effects of auto-inoculation may help to explain the comparatively favorable results obtained in some of the later operations, though it would be pushing the idea beyond reason to base upon it any defence of delay. Yet I am sure that every surgeon present must have occasionally felt surprised when, in operating on these slow or so-called chronic cases of appendicitis, he has contrasted the relative mildness of the symptoms with the enormous quantities of fetid pus under high pressure which he sometimes evacuates.

CASE XI.—I saw recently, in consultation, a case in which *there were practically no general symptoms* beyond a temperature of 100° F., a furred tongue, and some malaise. The patient had been out of bed within a day or two. The physician in attendance declined to believe in the presence of pus, which seemed to me indicated by the local symptoms. He assented, however, to an operation, which showed the presence of *twelve ounces of markedly fetid pus*, the first gush of which came with such force that it was projected a foot or more from the patient.

The best immediate indication of gross perforation of the appendix, with escape of its contents into the general cavity, is sudden violent excessively acute pain, followed by rapid change of temperature, either rise or fall, and marked increase of pulse-rate with diminution of volume and force. If the sepsis be profound the belly may be flat; if a little less in degree it may be barrel-shaped. Vomiting is usually a conspicuous symptom of this, as it is of other forms of perforative peritonitis, except that resulting from perforation of the stomach. It often shows its usual inverse relation to normal peristalsis. In eight cases of perforative peritonitis in which the bowels moved freely up to the time of the accident, constipation immediately followed in five. In these the vomiting

was much more marked and persistent than in the remaining three where the bowels continued loose (Treves).

Of course in these cases operation must be immediate, and even then the mortality has been, and doubtless will be for many years, enormous.

*Recurrent and Chronic Relapsing Appendicitis.*

—There remains to consider briefly the subject of recurrent and of chronic relapsing appendicitis. Here again the most diverse views exist, and we are brought back to our original starting-point as a basis for discussion. If, as I believe, various mechanical factors enter into the production of acute attacks, and if quite commonly those factors are brought into play by digestive derangement, and if an acute attack does not of necessity leave a permanent lesion of an infectious type, it is obvious that a patient may have two or even more mild attacks and safely decline operation. If, however, after any and every inflammation of the appendix, the patient is left, as has been asserted, with what is practically a charge of dynamite in the abdomen, operation should be much more frequent than it has yet become.

We shall do well, both in discussion and in practice, to separate the recurrent from the chronic relapsing cases. The former are well illustrated by the following case.

CASE XII.—In December, 1889, a gentleman aged thirty-eight had a mild attack of catarrhal appendicitis. He was ill for two or three days; was out of bed in four days. He was treated by rest, starvation, salines, and calomel. *His attack followed immediately upon a too hearty meal of broiled lobster after a day's shooting.* In 1890 he was in New York and on a visit, and had another attack. I was telegraphed for and went over to see him, meeting in consultation a well-known surgeon who had been called in at once. We agreed as to the undesirability of an operation at that time, but later disagreed, the New York surgeon advising removal of the appendix as soon as convalescence was established and I dissenting. I based my advice on the fact that the second attack, like the first, was clearly due to over-eating when tired, and especially on the circumstance that *it again followed a meal of broiled lobster.* Moreover, neither attack had been of a dangerous type. The opposing views were submitted by the patient, at my suggestion, to Dr. Agnew, who decided in favor of delay, and subsequently to Mr. Treves in London, who coincided in that opinion. The patient has never had another attack.

I have seen many such cases, and I am sure that this will be the testimony of the medical men who are most capable of informing us on this branch of the subject. At present I feel quite clear that the outcry for operation after one or two *such* attacks is based on conceptions of the etiology and pathology of the disease which are so incorrect that they entirely vitiate the arguments founded upon them.

In chronic relapsing appendicitis the case is somewhat different. The interval then is not one of entire health; there are digestive disorders, flatulence, constipation or diarrhoea, and pain in the right iliac fossa, aggravated by motion, or exercise, or fatigue. The attacks themselves are of a higher grade of severity, are accompanied by the appearance of a tumor, which often never entirely disappears, and by distinct evidence of localized peritonitis. The general health suffers severely, and the patient is apt to be anæmic and emaciated. I have observed this especially in females.

CASE XIII.—In a case sent me from Bellefonte, Pa., by Dr. Seibert, the child, a little girl aged ten years, was reduced to a condition of such *chronic invalidism and exhaustion* that even during an interval it was a question whether she could survive the journey to Philadelphia; and yet the operation was of the easiest type, completed in ten minutes without trouble. The appendix was thickened and twisted and diseased, but had no important adhesions. *The improvement in health was immediate* and has been continuous.

In the majority of these cases which finally require operation, especially in those in which the persistence of the local symptoms during the interval is marked, pus is present in small quantity and surrounded by thick, firm adhesions.

CASE XIV.—On the other hand, as in the acute cases, very great local disease may be attended with almost no constitutional phenomena. In a patient of Dr. Fussell's I found a *degree of inflammatory thickening and of fusing together of cæcum, appendix, omentum, small intestine, and parietal peritoneum that nearly made the operation impossible* and excited in my mind grave fears for the ultimate result, *and yet the boy had been walking and playing and complaining of local pain only occasionally, and he made a rapid and uninterrupted recovery.*

CASE XV.—In a patient of Dr. Russell Johnson's, on whom Dr. Agnew and I operated,

there had been so *large a number of attacks, brought on by exertion*, that the young man was almost afraid to stir out of the house, and yet he was a *picture of health and was not in the least affected in spirits or otherwise*. The local pain was simply so severe that while it lasted it was crippling. The appendix was adherent to the brim of the pelvis.

CASE XVI.—A *healthy, robust* woman, sent to me by Dr. Snyder, of White Haven, had had between *one hundred and two hundred attacks*. The appendix was angulated and buried in a mass of omental adhesions.

The diagnosis may usually be made by the history, the localized pain, the variable tumor, etc. Not infrequently, especially where the early stage of a malignant neoplasm is suspected, the only possible diagnosis is by exploratory incision.

Even these cases do not invariably require operation. In some instances I have suggested it, and then have acquiesced in the patient's request for a period of delay, which has now in several cases extended over some years and seems likely to be permanent. Treves, who originally proposed the operation in 1877, has thought it necessary within a year to call attention to the fact that it has been performed recently without proper discrimination, and adds, "The circumstances which would justify an operation in these cases must be precisely defined, and it cannot be too emphatically stated that, in a fair proportion of instances in which the trouble has relapsed, no surgical interference is called for. "I am aware of many cases in which a patient has had three or more attacks of typhlitis, and has then ceased to be troubled with any further outbreaks. In some examples of the relapsing form much can be done by medical means, by diet, by attention to the bowels, and by placing the patient under conditions more favorable to a state of peace within the abdomen."

Here again, also, we have the old fable about the mortality of the operation being "practically *nil*," but Bull's statistics, just published, show a mortality of nearly two per cent., and he remarks that if he could add four fatal cases that he is aware of, it would be raised to more than two per cent., and, further, that five or six per cent. would be a fairer estimate if we struck an average of the work of individual surgeons. There is, however, good reason for believing that the mortality for the operation in skilful hands will be a low one. The experiments of Reichel, already alluded to, de-

monstrate beyond a doubt the possibility of a certain immunity resulting from auto-inoculation with pyogenic material. There seems to be good reason for believing that this comparative invulnerability thus acquired renders the peritoneum more indifferent to traumatism than in its normal condition. (See Case XIV.) It is a clinical fact that an intraperitoneal operation on a subject who has had several attacks of subacute or chronic peritonitis is, *ceteris paribus*, a less serious affair than if the same operation is done on a patient whose peritoneum has hitherto been uninvaded by disease or for operative purposes. Treves says as to this point, "In the operation for the removal of the vermiform appendix in cases of relapsing typhlitis, the little disturbance which follows extensive procedures occupying as long as one hour and a half can, I think, be explained only by an immunity acquired by the peritoneum after repeated attacks of inflammation. Moreover, in advanced cases the disproportion which is often noted between the constitutional disturbance and the local condition discovered at the operation appears to be capable only of the same explanation."

CASE XVII.—In another relapsing case just operated on for Dr. Fussell the appendix was buried in dense adhesions posterior to the cæcum, and was firmly adherent by its tip to the iliac vein. The union was so intimate that I tied off both tip and base and removed the intermediate portion, which showed a small perforation. There was present a general plastic peritonitis. The patient, who had only recently recovered from a severe attack, *was extremely emaciated and had the typical facies abdominalis*, and yet *six hours after the operation*, which took three-quarters of an hour, *his temperature was normal, his pulse 102, he had a movement of the bowels, and expressed himself as feeling better*. He is now making an excellent recovery.

If the indications for operation are clear, I think the question as to whether it shall be done between or during attacks must be unhesitatingly decided in favor of the period of quiescence, the operative difficulties being then much less, especially as regards the important question of possible general infection. In the recurrent type, if operation is to be considered at all, it would be well to take the inappreciable risk of waiting for another attack, which may never come.

In the chronic relapsing cases, however, if the surgeon, in deciding upon operation, limits himself to the following indications formulated

by Treves, which fairly express those of many surgeons in this country, myself included, he had far better take advantage of the interval. Operation is indicated when: 1. The attacks have been very numerous. 2. The attacks are increasing in frequency and severity. 3. The last attack has been so severe as to place the patient's life in considerable danger. 4. The constant relapses have reduced the patient to the condition of a chronic invalid and have rendered him unfit to follow any occupation. 5. Owing to the persistence of certain local symptoms during the quiescent period there is a probability that a collection of pus exists in or about the appendix.

The operation itself may be one of the easiest in abdominal surgery, or so difficult as to be impossible in its entirety, if due regard is had to the survival of the patient. (See Case XIV.)

There are no very radical differences of opinion as to its technique, so the details need not be mentioned. Such differences as do exist relate chiefly to the symptoms and conditions which demand or which justify the operation. Bull has well expressed the situation in this respect: "We need more carefully recorded cases not only of the patients who come to operation, but of those who have successive attacks relieved by medical measures. There are many gaps to be filled between the position of the surgeon who operates only when there are definite symptoms of chronic disease which have been found by operation to correspond with definite lesions of the appendix, and those who resort to operation after one or two attacks in individuals who have no symptoms, because they believe future attacks must occur in the order of nature and must endanger life. The position of the former may be too conservative, but I think it is 'up to date' with the knowledge we have at present. The attitude of the latter is unscientific, as their statements are not borne out by demonstration."

It is just to say, in conclusion, that, while I see no reason for joining in the outcry about the claims of appendicitis to be considered a purely surgical disease, the sum total of the relations of surgery to appendix troubles reflects the greatest credit upon that branch of the profession both in this country and abroad. The beneficent work done by surgeons has now fully established their right to be early participants in the management of cases to the later and more unfavorable stages of which they are so frequently called. Altogether apart from the extravagant claims of extremists, it is certain that the field of operative surgery in this disease is a steadily widening one, and that as

time goes on and the joint labors of progressive yet duly conservative men in both medicine and surgery begin to bear their fruit, we shall save, by increasing precision and exactness in diagnosis and treatment, many lives now unavoidably sacrificed.

The views above expressed may be summarized as follows:

1. The explanation of the great frequency of inflammation of the appendix is to be found in the following facts:

(a) It is a functionless structure of low vitality, removed from the direct faecal current; it has a scanty mesentery so attached to both cæcum and ileum that it is easily stretched or twisted when they become distended; it derives its blood-supply through a single vessel, the calibre of which is seriously interfered with or altogether occluded by anything which produces dragging upon the mesentery.

(b) In addition, there is almost always present a micro-organism—the *bacterium coli commune*—capable of great virulence when there is constriction of the appendix or lesions of its mucous coat or of its parietes.

2. The symptoms in a case of mild catarrhal appendicitis—general abdominal pain, umbilical pain, localized pain and tenderness on pressure in the right iliac fossa, vomiting, moderate fever, and slightly-increased pulse-rate—cannot at present with any certainty be distinguished from the symptoms, apparently precisely identical, which mark the onset of a case destined to be of the very gravest type.

3. It must be determined by future experience whether or not operation in every case of appendicitis, as soon as the diagnosis is made, would be attended by a lower mortality than would waiting for more definite symptoms indicating unmistakably the need of operative interference. At present such indication exists in every case if the onset is sudden and the symptoms markedly severe, and whenever in a mild case the symptoms are unrelieved at the end of forty-eight hours, or, *a fortiori*, if at that time they are growing worse.

4. It must be determined by future experience whether cases seen from the third to the sixth day, which present indications of the beginning circumscription of the disease by adhesions and which tend to the formation of localized abscesses, will do better with immediate operation with the risk of infecting the general peritoneal cavity, or with later operation when the circumscribing wall is stronger and less likely to be broken through. At present, operation is certainly indicated whenever a firm, slowly-forming, well-defined mass in the

right iliac fossa is to be felt; or, on the other hand, when a sudden increase in the sharpness and the diffusion of the pain and tenderness points to perforation of the appendix or breaking down of the limiting adhesions.

5. In the beginning of general suppurative peritonitis, operation offers some hope of success. In the presence of general peritonitis with septic paresis of the intestines, operation has thus far been useless.

6. Recurrent appendicitis of mild type, like acute appendicitis, frequently results from digestive derangements. Several attacks may occur followed by entire and permanent recovery, but it is as yet impossible to differentiate these cases accurately from those which do not tend to spontaneous cure. Operation is certainly indicated whenever the attacks are very frequent.

7. Chronic relapsing appendicitis is characterized by the persistence of local symptoms during the intervals and by more or less failure of the general health. It usually indicates operation.

8. In either the recurrent or the chronic relapsing variety operation should be advised according to the following indications formulated by Treves: whenever (1) the attacks have been very numerous. (2) The attacks are increasing in frequency and severity. (3) The last attack has been so severe as to place the patient's life in considerable danger. (4) The constant relapses have reduced the patient to the condition of a chronic invalid, and have rendered him unfit to follow any occupation. (5) Owing to the persistence of certain local symptoms during the quiescent period, there is a probability that a collection of pus exists in or about the appendix.

#### TREATMENT OF ALCOHOLISM BY STRYCHNINE NITRATE.

BREED concludes a paper in the *Medical News* of April 7, 1894, on this subject as follows:

1. That we have in this drug a remedy that actually, for a period as yet undetermined, removes the desire for alcoholic stimulation in the chronic inebriate, and that *without the least effort on his part*.

2. A remedy that removes the distress and gnawing at the epigastrium, so common upon the withdrawal of alcohol.

3. A remedy that tones up the nervous system, allays the insomnia, the flighty and other bad feelings in the head, the mental disturb-

ances, and the tremulous agitation and uncertainty of voluntary motions due to the withdrawal of stimulants.

4. A remedy that brings back the appetite and general physical vigor of the body.

5. A remedy that temporarily transforms a wholly demoralized creature into a man.

6. A remedy that is of great value in acute attacks of alcoholism.

7. Incidentally, a remedy that is an exceedingly good and safe heart-tonic.

8. More than all, a remedy that exerts a moral influence upon the patient, giving him what he had before wholly lost,—to wit, hope, enthusiasm, self-confidence, and courage, where before was despondency, abandonment, and despair; a steady, straightforward gaze, and a bright, youthful expression of the eye, which replaces the shamefaced, sneaking, apologetic air of total depravity of the chronic inebriate.

9. We have in the nitrate of strychnine not a remedy that will oblige a man to abstain from drink if he does not want to do so, and such subjects do not deserve one. From the results obtained by the gold cure, the silver-ash cure, the Keeley cure, etc., we may conclude that we have a remedy that is as efficient as any of these and much safer; a remedy, moreover, that is not secret, and can be used by men who know the action of drugs and can use them with discretion and safety to the patient.

#### THE EFFECTS OF QUININE ON PREG- NANCY.

A collective investigation of this subject is published in the *Indian Medico-Chirurgical Review* for February, 1894, the results of which are as follows:

1. The existence of pregnancy is no bar to the administration of quinine.

2. For fevers and other affections during pregnancy in which quinine is indicated the effects of the drug are more marked than those of any other.

3. That abortion following the administration of quinine is either the result of the original malady or the effect of idiosyncrasy.

4. That allowing for an idiosyncrasy, in cases in which a tendency to abortion exists, and in others as a matter of precaution, quinine is best administered combined with a sedative (opium).

5. Hence the old-standing view of the action of quinine on the duration of pregnancy is not borne out by the clinical experience collected in the replies.

### THE VALUE OF BOILED MILK AS AN ARTICLE OF DIET.

EVERY practitioner of medicine knows that in the treatment of certain cases of diarrhoea, where an absolute milk diet is required, better results follow the use of boiled milk than of raw milk, and for this reason it has become a popular idea among the laity and members of the profession that cooked milk is the more digestible. However this may be in clinical experience, it is certain that experimental research does not justify this conclusion. Ten years ago the late Dr. Randolph, of Philadelphia, made an interesting series of experiments to determine this point. A number of men in perfect health were given raw milk to drink; an equal number, equally healthy, were given a similar quantity of boiled milk. An equal time after the ingestion of the liquid a hypodermic injection

of apomorphine was administered to each, and a careful examination made of the vomited matters to determine how far the process of digestion had proceeded. In every instance it was found that the raw milk was more digested than the cooked, and as Randolph graphically expressed it, "We obtained proof that in making milk, nature made that compound most easy of digestion."

The experiments of Crolas, on the other hand, seem to point to a different result, for he believes as a result of his studies that boiling has no action whatever on the casein or lactose, and removes from the liquid a small quantity of butter, which is entangled with the film of albumin which forms on the surface of the milk. He also thinks that boiling increases the quantity of the free soluble phosphates, and concludes, in opposition to the studies of Randolph, that boiled milk is equivalent, if not superior, to raw milk.

The correct solution of the problem probably lies in the class of cases to which the milk is administered. There is no doubt whatever that raw milk is more digestible than boiled to the healthy individual, and it is an undeniable fact that boiled milk is far more constipating, and that an attempt to place a patient upon a diet of boiled milk would more certainly tend to disorder digestion and assimilation than a similar attempt with the raw article. In Bright's disease, diabetes, and similar conditions in which a milk diet is desirable, we may therefore conclude that raw milk is the liquid to be employed, whereas, in cases of diarrhoea, the boiled milk is by far the best preparation. We have already pointed out in earlier leading articles that both raw and boiled milk have their digestibility very much increased by being somewhat diluted with any sparkling water, or by the addition of a sufficient quantity of salt to give a distinct flavor.

### THE TRUE VALUE OF METHYLENE-BLUE IN MALARIAL FEVER.

THE readers of the THERAPEUTIC GAZETTE who have carefully read the articles upon methylene-blue in the Progress columns during the last year must have obtained views very much in accord with our own concerning the value of this new medicament in paludal disease. It has now been tried in a sufficient number of cases of all kinds and all ages to give us sufficient ground to reach fairly positive conclusions as to its value. The studies of Ferreira upon the action of the drug in chil-

dren, those of Thayer in Baltimore, and of a number of other investigators in Europe and America seem to prove very positively that the drug is of value in all cases of malarial disease, although it does not possess the powerful antiperiodic properties of quinine. Its therapeutic indications, therefore, point to its employment in those persons who have an idiosyncrasy to quinine, or in those in whom quinine has failed to produce as beneficial results as is desired. The best way to administer it is in capsule or solution, in the dose of 2 to 3 grains twice or thrice a day, attempting to administer the fullest doses in cases of intermittent fever about two or three hours before the time at which the malarial attack is expected. It should be remembered that in some persons methylene-blue produces disagreeable symptoms, which generally consist chiefly in signs of irritability of the bladder. If these symptoms are excessive, it is possible that the methylene-blue is contaminated by arsenic. An important point in regard to its successful use in malaria is the fact that it must be continued for some time after all malarial manifestations have disappeared; indeed, after careful blood examination fails to show any signs of the malarial organism. A disadvantage in its use is the fact that relapses seem to occur with greater frequency in those who are supposed to be cured than in similar cases which have experienced relief from full doses of quinine.

#### *INTESTINAL INDIGESTION WITH FERMENTATION.*

IN an earlier number of the THERAPEUTIC GAZETTE we wrote a leading article upon the employment of creosote in the treatment of gastric indigestion associated with fermentation. There is another class of patients who suffer equally severely, not so much from gastric disorder as from the accumulation of large amounts of flatus in the small and large intestine, as the result partly of constipation and partly of atony of the duodenum in its digestive function. Frequently these patients suffer severely from pain in the region of the præcordium, which is so severe as to bring them to the doctor's office with the fear that they are suffering from cardiac disease. As a general rule no cardiac lesion will be discovered, but in its place there will be found evidences of dilatation of the transverse colon and a general tympanitic condition of the entire belly, with a particularly high pitched tympanitic note near the præcordium about the point where the

transverse turns to become the descending colon. It is at this point that the gas which is produced becomes lodged and reflexly causes not only pain, but marked cardiac palpitation. In other instances the pain is felt at other portions of the alimentary canal, and in nearly every instance the resulting discomfort is sufficient to make the patient very grateful for relief. In a certain proportion of cases this symptom disappears under the administration of a prescription, as follows:

R Salol, ʒi;  
Pancreatin, gr. xl;  
Oleoresin capsici, ʒxx.  
M. Ft. in pill No. xx.

If this is prepared by a careful druggist the patient will have no difficulty in swallowing the pill because of its size.

#### *THE DOSE OF GRAY OIL AND BICHLORIDE OF MERCURY HYPODERMICALLY IN SYPHILIS. A CORRECTION.*

THROUGH an error, the dose of gray oil was given as 10 to 20 minims in the editorial entitled "The Treatment of Syphilis by Hypodermic Injections," on p. 327 of the issue of May 15, 1894. The amount should have been 1 to 2 minims. The dose of bichloride of mercury recommended—namely,  $\frac{1}{10}$  grain—may be rapidly increased, if the patient stands the drug, to  $\frac{1}{4}$  or  $\frac{1}{2}$  grain, but  $\frac{1}{10}$  grain is not too small for a beginning dose.

#### *TREATMENT OF HYPERTROPHIED PROSTATE BY CASTRATION.*

IN the November, 1893, number of the THERAPEUTIC GAZETTE there appeared an editorial calling attention to the surgical treatment proposed by J. William White for the relief of the bladder symptoms dependent upon hypertrophy of the prostate. White, basing his conclusions upon a series of observations upon animals and on the post-mortem findings in the case of eunuchs, came to the conclusion that the prostate was a sexual organ dependent for its development on the presence of the testicles, and that by removal of the latter this gland could be made to atrophy. His laboratory experiments, conducted by Kirby, having proved the truth of these propositions, he further argued that an hypertrophied prostate would probably undergo similar atrophy in case the testicle is removed, this thought no doubt being

suggested by the effect of removal of the ovaries upon fibroid tumors of the uterus.

Griffith arrived at conclusions practically identical with those of White, excepting that he did not propose removal of the testicles as a means of curing prostatic hypertrophy. Since the publication of the leading article above referred to this proposition of White's has been practically carried out by himself and others with most gratifying results.

Ramm (*Centralblatt f. Chirurgie*) reports two cases of prostatic enlargement cured by double castration. The first case was kept constantly under observation after operation until the last of December, 1893. The prostate, which before operation was the size of a medium-sized orange, was shrunk into an almost flat mass. The patient during the day passed his water as well as ever, and was required to rise three times only during the night.

The second patient, sixty-seven and a half years old, was operated on in April, 1893. He first reported to the hospital in 1887 for the relief of urinary retention, and gave a history then of having suffered for fourteen years with difficulty in passing his water. After being relieved at this time he continued to suffer from attacks of retention, and had to use a catheter at intervals, sometimes repeatedly during a single hour. In 1892 suprapubic puncture was made. At this time the patient was suffering from cystitis, the bladder was distended until it reached to the umbilicus, the prostate was huge, and catheterization most difficult; the urine was extremely offensive. On the night following castration the patient passed his water without the use of an instrument. In two weeks the prostate was markedly lessened in size. The third week the bladder was completely evacuated by voluntary effort, the patient urinating five to seven times during the day. Six weeks later, in the erect posture, he could urinate without trouble, projecting a stream outward for a distance of twenty inches. At the time of reporting the prostate as atrophied the patient was never compelled to use a catheter, he urinates four or five times a day, once at night, has no symptoms of cystitis, and is practically able-bodied.

Ramm concludes as a result of his studies that the prostate is a sexual organ, is an organ which develops at puberty, and that malformations and early castration cause it to remain undeveloped, and even after it has attained its full growth castration will cause it to atrophy; that hypertrophied prostate will also atrophy after castration, this lessening in volume beginning almost immediately and continuing

until the enlargements entirely disappear; and, finally, that the fact that castration may cause atrophy of the prostate is of the highest therapeutic importance, since there is thus given a means by which obstruction to urine when it depends upon prostatic enlargement may be safely and permanently removed.

In the paper read by White before the genito-urinary surgeons, May 29, a number of other cases were detailed. It is worthy of note that in practically all obstruction symptoms were markedly relieved within the first one or two days, that the atrophy of the prostate was rapid and progressive, and that cure was complete. The operation itself is practically free from danger. It implies the removal of organs which, from the advanced age of patients suffering from enlarged prostate, are no longer functional, and it promises a speedy cure of an affection in the treatment of which most surgeons are content with palliation, and the only radical treatment heretofore proposed—*i.e.*, prostatectomy—still showing such a large death-rate that there is a natural hesitation in recommending it to those who by simpler and less radical means may be made to enjoy many years of comparative comfort. This comfort is, however, only comparative and does not compare with the relief which they would experience with the obstruction to urine entirely removed. Still, more cases are needed before the merits of this operation will be clearly appreciated, yet a sufficient number have been brought to fully justify the surgeon in castration in suitable cases.

---

#### INTRAOCULAR INJECTIONS OF ANTISEPTIC SUBSTANCES AS A THERAPEUTIC MEASURE.

---

WE have on more than one occasion referred to subconjunctival injections, particularly of bichloride of mercury, as measures suited to control infection processes,—for example, sloughing of the corneal tissue,—or to relieve the manifestations of ocular syphilis, especially when located in the uveal tract, and in the Progress columns of the GAZETTE the most important papers bearing upon this subject have appeared in abstract. In the main, the conclusion has been reached that this is a therapeutic procedure worthy of respect and that it deserves further trial.

To a certain extent these subconjunctival injections, in their modern revival, are an outcome of a proposal by Abadie to control sympathetic ophthalmitis by introducing into the vitreous chamber 2 minims of a 1 to 1000 solu-

tion of sublimate. Indeed, this surgeon, in 1890, not only proposed this plan of treatment, but published the records of cases in which he had successfully employed it. After his announcement occasional reports appeared in the journals confirming his observations, but more frequently the experience of those who followed this recommendation was such that the method was practically abandoned. Abadie himself expressed his willingness to substitute for it subconjunctival injections, provided the latter were proved to be more efficacious, and in August of the past year he gave distinct preference to the subconjunctival injections, although still maintaining that indications for intraocular medication occasionally presented themselves.

Comparatively recent experimental inquiry concerning the effects of intraocular injections of various antiseptic substances has revived interest in the matter, and during the meeting of the International Ophthalmological Congress, to be held in August of the present year at Edinburgh, there will be a special session devoted to this subject.

Two researches bearing directly upon the matter have appeared within the past year, the one by the writer of this article, carried on in the Laboratory of Experimental Therapeutics in the Jefferson Medical College and published in the *Journal of the American Medical Association*, October 21, 1893, and the other by Dr. Chasseaud, from the Laboratory of the Royal College of Physicians in Edinburgh and recorded in the *Journal of Pathology and Bacteriology*, November, 1893, a brief notice of which had previously appeared in the *Ophthalmic Review*, December, 1892.

These experimenters injected various antiseptic substances into the vitreous chamber of rabbits, and noted the effect with the ophthalmoscope and later with the microscope. In the American research the injections comprised bichloride of mercury (1 to 500, 1 to 1000, and 1 to 5000, respectively), cyanuret of mercury (1 to 1000), aqua chlorinata (official strength), blue pyoktanin (1 to 1000), and bichloride of iodine (1 to 1000). The list of drugs employed by Dr. Chasseaud was more extensive, and included corrosive sublimate, carbolic acid, tincture of iodine, camphorated naphthol, hydronaphthol, eucalyptol, boric acid, iodoform, oxycyanide of mercury, peroxide of hydrogen, creolin, pyoktanin, and aqua chlorinata.

Both experimenters found that the last-named drug could be introduced into the posterior chamber of the eye without serious disturbance, and Dr. Chasseaud has reached the

conclusion that it is the only substance which fulfils the necessary conditions for a useful intraocular antiseptic, although he is convinced that various fluids may be injected into the vitreous with safety. He found that corrosive sublimate and carbolic acid, owing to their stable compounds with albumin and the inflammatory reaction which they produce, are not so useful as some other less powerful antiseptics; that tincture of iodine, camphorated naphthol, hydronaphthol, and other antiseptic oils are far too violent in their action and cause disorganization of the eye; that boric acid and iodoform are weak and non-irritant; that oxycyanide of mercury and peroxide of hydrogen are good antiseptics, but cause opacities in the vitreous; that creolin is doubtfully antiseptic and very irritant; and that pyoktanin gives rise to neuritis and degeneration of the optic nerve.

The writer's results were less encouraging, as in twenty-four eyes, injected with the substances previously named, only one escaped positive permanent lesion, easily visible with the ophthalmoscope, and situated in the vitreous, choroid, or retina. The one exception, as before mentioned, occurred with aqua chlorinata. Neither were the effects of these substances potent in checking purulent inflammation called into existence by staphylococci emulsion injected into rabbits' eyes; but in one mongrel cur a hyalitis was apparently cured by sublimate injections.

It is evident, then, that there is some hope that aqua chlorinata may prove a useful intraocular antiseptic, although how far these results may be applicable to man, as Dr. Chasseaud concludes, it would be difficult to say. Evidently, as the writer suggested in his first paper, and as Dr. Chasseaud also indicates, a series of control experiments should be performed on dogs, and the study of the relations of the chemical composition of the vitreous to that of the fluid injected should be more exact.

---

## Reports on Therapeutic Progress.

---

### THE ACTION OF THE CARLSBAD THERMAL WATER ON THE STOMACH FUNCTIONS.

JAWORSKI has investigated the action of the Carlsbad thermal water, and found that it excited the secretion of acid and pepsin by the stomach and promoted the passage of the stomach's contents into the intestine. When, however, it was used for from four to six weeks, he

found that the acidity of the stomach was diminished, the secretion of pepsin steadily lessened, the resorptive power suffered, so that in certain cases no irritant longer sufficed to obtain gastric juice of digestive power. On too long use of the water the digestive power was wholly lost. Only in a small number of cases were acidity and digestive power raised. The mechanical function seemed likewise in a few cases to be increased.

These unexpected results induced Ewald and Sandberg to try the water for four weeks in the case of ten persons. Their results contradict Jaworski's.

Finally, W. SPITZER (*Therapeutische Monatshefte*, April, 1894) endeavors to solve the question. Having first satisfied himself that single doses of the water promote the gastric secretion in healthy individuals, he examined systematically eighteen persons suffering with gastric disorders. Of the eighteen, five suffered with chronic mucous catarrh, two of them with severe grades (atrophy?); three had excess of HCl (one with motor insufficiency); one had cancer of the stomach (?) with motor insufficiency; three had pure atony; six suffered with various forms of nervous dyspepsia (an-acidity, nervous eructations, gastralgia, etc.). The persons experimented on received early in the morning, fasting, the thermal water and Carlsbad salt; one hour later an Ewald test-breakfast; the gastric contents were removed in from one to two hours later.

The results obtained are as follows:

1. In most of the cases the motor power was increased; in none of them was it injured. The result was most decided in the cases of motor insufficiency which were not too severe. Even in the doubtful case of cancer, in which in the first days a residue of about three hundred cubic centimetres was expressed from the fasting stomach, after three weeks' use of the water the stomach was found empty one and a half hours after the test-breakfast.

2. After the completion of the cure the pepsin action showed no essential diminution in cases where it had been present at first, and in the mild cases of chronic catarrh there was a decided increase.

3. The HCl secretion varied, but only within physiological limits. The superacid values sank to normal, but not essentially lower. The two cases of atrophic gastritis exhibited after, as they did before, treatment no trace of HCl. But the doubtful case of cancer which showed before notice free HCl exhibited it afterwards in profuse quantity.

4. The pepsin action proved not to be de-

pendent upon the acidity, so that when the acidity fell the pepsin secretion showed no diminution.

5. The rennet ferment showed, on quantitative testing, never a diminution, but often an increase.

#### METHYLENE-BLUE IN MALARIAL AFFECTIONS.

ERNST FRATNICH (*Therapeutische Monatshefte*, April, 1894), following Guttman, has employed methylene-blue in four cases. The urine was stained intensely blue, but contained no albumin. No strangury occurred. The stools and saliva were intensely blue. Plasmodia were demonstrated in the blood in two cases. The remedy seems to have stopped the fever and cured the patient in three of the cases. In the fourth case quinine was administered by mistake.

#### THE TREATMENT OF CHRONIC RHEUMATISM.

We published not very long ago an abstract of an article by DUJARDIN-BEAUMETZ on the treatment of acute articular rheumatism. The same author has in a later contribution (*Bulletin Génér. de Thérapeutique*, February 15, 1894) critically examined the therapeutics of the chronic form of the disorder. In that form of rheumatism, accompanied with deformities, with no history of an acute attack or of cardiac lesion,—as that, for example, which constitutes gout of females,—the medication should better be directed towards combating a disordered nutrition. It is in this condition that arsenic and the iodides appear to be better indicated. Arsenic, however, is often followed by painful phenomena, and it is in these cases that iodine or the iodides should be exclusively used. The iodides are to be preferred, and the following prescription is recommended:

R Iodide of potassium, 4 drachms;  
Water, 8 ounces. M.

Sig.—A dessertspoonful in sweetened black coffee after each principal meal.

The chloride of gold and sodium, recommended by some practitioners, the author believes to be irritant, notwithstanding its alleged beneficial influence over nutritive processes. In cases of rheumatism attended with painful symptoms the salicylates do no good, and the only remedy that has apparently given satisfactory results in such cases is phenacetin, particularly paracetphenetidin in doses of .5 gramme, twice or thrice a day, in the form of cachets. Besides internal medication, diet is of the utmost

importance; the latter should consist of meats well done or rare, green vegetables, generous wines, and the use of milk, especially while the patient is taking the iodides. To make the treatment more complete, massage, electricity, and balneotherapy should be added under proper conditions.

In the true form of chronic rheumatism, particularly in the acute stages, the salicylates, asaprol, and more rarely phenacetin, may be employed with advantage. Certain other remedies are of service not only for the time being, but also to prevent relapses. The author refers to the following mixture, alleged to be advantageous, but which he has not employed, mentioning it only on account of its popularity:

- R Powder of colchicum bulbs, 5 drachms;  
 Powder of bryonia root, 3 drachms;  
 Powder of betony, 12 drachms;  
 Powder of gentian, 3 drachms;  
 Powder of common chamomile, 3 drachms.  
 M. and divide in 15-grain powders.  
 Sig.—2 powders a day.

Another plant thought to possess remedial virtues in chronic rheumatism is the bean, especially the flowers. But, after all, the best results in this form of the disease are obtained from external medication, and it is these cases in which massage, electricity, and balneotherapy are of peculiar advantage. Massage, methodically applied, combats not only the functional weakness of the articulations, but especially so the muscular atrophy accompanying this kind of arthritis. Electricity, through the continued or slowly-interrupted currents, also modifies the atrophied muscles. The utility of balneotherapy is unquestionable, particularly by means of thermal waters. Diet, of course, is important. Without entirely suppressing meat or wine, a mixed diet, with a large amount of vegetables, is to be preferred. Highly-seasoned food should be avoided. The condition of the bowels and kidneys should claim attention; the regularity of their functions should be maintained by the administration of proper laxatives and diuretics. The latter treatment may also be applied to rheumatic diathesis, where, indeed, hygiene and balneotherapy are the most important measures to be employed.

#### THE TREATMENT OF DIARRHŒA.

Under the above title, SAPELIER (*Bulletin Génér. de Thérapeutique*, February 15, 1894) writes an exhaustive article. For the indigestion that accompanies the disorder he believes that an expectant treatment, diet, and stimulants

are sufficient. To enhance the elimination of toxines resulting from the indigestion, saline purgatives are indicated. In *acute intestinal catarrh* saline purgatives are of service, followed by the administration of this mixture:

- R Purgoric, 1 to 3 drachms;  
 Subnitrate of bismuth, 1 to 2 drachms;  
 Extract of rhatany, 1 drachm;  
 Syrup of comfrey, 2 ounces;  
 Lime-water, q. s. for 5 ounces. M.

Sig.—A dessertspoonful every two hours, according to indications.

A milk diet, bouillon deprived of all fat, and lactated or plain lemonade are to be conjoined.

In *chronic intestinal catarrh* antiseptic purgatives are to be employed, the first of which is calomel in large quantities (8 to 10 grains at one dose) or in fractional amounts (1 to 2 grains a day during several days). Opium may be associated. Regarding intestinal antiseptic remedies, the author speaks of the salicylate of bismuth, betol, salol, benzonaphthol, benzoate of bismuth, dermatol, resorcin, lactic acid, etc. The salicylate or the benzoate of bismuth may be given in doses of from 30 grains to 6 drachms a day; salol, in from 15 to 45 grains every twenty-four hours, in cachets of 8 grains each; the same dosage is mentioned for betol. Lactic acid is recommended in the form of a lemonade, according to the following formula:

- R Lactic acid, 5 drachms;  
 Simple syrup, 6 ounces;  
 Boiled water, 1 quart.

The author also advises the use of benzonaphthol in doses of 1 drachm during the twenty-four hours, in cachets of 8 grains each. The association of opium is thought to be of service, and the following combination is recommended:

- R Subnitrate of bismuth, 8 ounces;  
 Carbonate of calcium,  
 Phosphate of calcium,  
 Powder of rhatany, of each, 2 ounces;  
 Powder of crude opium, 45 grains.

This is to be administered in the lactated lemonade, in doses of from 2 to 3 dessertspoonfuls a day, each dessertspoonful containing 1 drachm of bismuth, 15 grains each of carbonate of calcium, phosphate of calcium, and the powder of rhatany, and 1 grain of the powder of opium. Owing to the disagreeable taste of the opium, it is advantageous to administer it in the form of laudanum in rectal injections of starch; 5, 10, or 20 drops

of laudanum are used for one injection, the injection being exhibited after each passage. These injections diminish the rectal tenesmus as well as the colicky pains.

In *hemorrhagic diarrhæa* recourse is had to the administration of the perchloride of iron by the mouth as well as by the rectum, associated with the hydrochlorate of morphine. In the same conditions alum is of advantage, and may be administered according to these prescriptions:

1. R Pulverized alum,  
Catechu, of each, 5 grains.  
M. and make four pills.  
Sig.—3 to 6 pills per day.
2. R Alum,  
Catechu, of each, 2 grains;  
Crude opium,  $\frac{1}{4}$  grain;  
Syrup of red roses, q. s.  
M. and make one pill.  
Sig.—12 pills per day.

For *chronic catarrhal diarrhæa* the treatment is thus summarized by the author: (a) Absolute milk diet; a small cup of milk should be taken in a slow manner every two hours. To this amount of milk may be added a dessertspoonful of lime-water or Vichy-water. (b) At the same time a cachet of either of the following combinations may be administered:

1. R Benzonaphthol,  
Benzoate of bismuth, of each, 5 grains.
2. R Benzonaphthol, 5 grains;  
Salicylate of bismuth, 8 grains.

Or,

R Dermatol, 5 grains.

(c) Similarly every two hours, but in the intervals between the cups of milk, a dessertspoonful of either of the following mixtures may be taken:

1. R Elixir of paregoric, 1 to 2 drachms;  
Tincture of catechu, 2 to 4 drachms;  
Syrup of comfrey,  
Syrup of quince, of each, 1 ounce;  
Peppermint-water, q. s. for 5 ounces.
2. R Extract of rhatany, 1 drachm;  
Syrup of morphine,  
Syrup of quince, of each, 12 drachms;  
Lime-water, q. s. for 5 ounces.
3. R Liquid perchloride of iron, 8 to 15 grains;  
Sydenham's laudanum, 20 to 30 drops;  
Mucilage of gum arabic,  
Simple syrup, of each, 1 ounce;  
Cinnamon distilled water, q. s. for 5 ounces.

(d) In the intervals between either of the preceding mixtures and the milk accompanied

with the cachets, the lactated lemonade mentioned before may be administered in glassfuls. (e) If there is much tenesmus, after each passage a starch injection with 5 or 10 drops of Sydenham's laudanum may be employed by means of a small syringe. (f) At the same time warm applications to the abdomen should be used, by means of flannel or rubber bags filled with warm water. If flannel is used, this may be dipped in the following liniment:

R Oil of hyoscyamus,  
Camphorated oil of chamomile,  
Rousseau's laudanum, of each, 1 ounce.

In the *diarrhæa* of warm climates the author refers to Le Dantec's prescription, which is as follows:

R Saturated chloroform-water,  
Distilled water, of each, 4 ounces.

Sig.—In teaspoonfuls by the mouth several times in the course of the day.

For *mountain diarrhæa* the best treatment is said to consist in the use of intestinal antiseptics, particularly the biniodide of mercury in solution, and pepsin. The mercury is given fifteen minutes before and the pepsin (in doses of 8 grains) two hours after each meal.

In the *diarrhæa of Asiatic cholera*, as well as in the simple choleraic forms of diarrhoea, salol in large doses is said to be an excellent remedy. In the epidemic of Asiatic cholera at Nijnii-Novgorod, in 1892, Volkovitch gave salol in doses of from 2 to 4 drachms in the twenty-four hours, beginning with 15 to 30 grains as the first dose, according to the condition of the patient, and then repeating the same amount every three hours, or every four, five, or six hours if improvement persisted. Under this treatment, in the first twelve hours the diarrhoea diminished and the passages ceased to be rice-water-like, and nausea and vomiting disappeared. No symptoms of poisoning by the drug were noticed, even when the remedy was employed in large quantities. To children, salol may be administered every three or four hours, in doses of two grains for each year of the age.

The treatment of *sporadic dysentery* is thus summarized, according to Grasset:

1. A draught of water before breakfast.
2. Followed, every two hours, by a bowl of milk, and with this a cachet of this combination:

R Benzonaphthol,  
Benzoate of bismuth, of each, 5 grains.

3. If this is not sufficient, a spoonful of the following mixture :

R Ipecacuanha, 1 to 2 drachms.

To be infused in 3 ounces of water, and to which is added 1 ounce of syrup of poppies.

4. Morning and evening a rectal injection of 1 to 2 pints of borated water of the strength of two per cent., followed by another injection of linseed (1 pint), with 15 to 150 grains of benzoate of bismuth and 10 drops of Sydenham's laudanum.

5. The patient is allowed to take gradually of ordinary mixed diet. The antiseptic cachets are continued for a long time.

6. A change of climate, as, for instance, a stay at a health resort.

*Syphilitic diarrhœa* yields to treatment by the specific remedies. The diarrhœa occurring in acute rheumatism, unless it be severe, is better left alone. That of *arthritis* requires a constitutional treatment. The *diarrhœa of tuberculous patients* may be treated in the same manner as the chronic form already referred to. When the diarrhœa is the result mainly of paludic intoxication, quinine, of course, is the remedy *par excellence*.

#### TREATMENT OF TUBERCULAR PERITONITIS BY INSUFFLATIONS OF AIR.

It has been demonstrated in some instances that air exercises a special action on tubercular peritonitis. It has been found sufficient to open the abdomen, exposing this to the air for a few moments, the procedure being followed often by a cure. Bearing these facts in mind, DURAN (*Revista de Ciencias Médicas de Barcelona*) has employed the following method in two cases of tubercular peritonitis accompanied with ascites. After evacuating the liquid by means of a common trocar,—in one case he removed eight litres (fourteen pints), and in the second case, twelve litres (21.1 pints),—he insufflated as much air as possible into the peritoneal cavity through the same trocar. The air had previously been made to pass through caustic potash moistened with phenic acid. The air was allowed to remain in the cavity for a few moments and then let out, after which a light compress was applied. The patients were somewhat feverish and had slight nausea during two days. Tympanitis persisted for about eight days and then it began to subside. Gradually the abdomen regained its normal size, and in about six weeks a complete cure was effected. These two cases are certainly

interesting, and the method employed seems to be worthy of further trial. Its application is, indeed, simple and devoid of danger as long as sufficient antiseptic precautions are taken.—*La Médecine Moderne*, March 3, 1894.

#### EXOTHYROPEXIA IN EXOPHTHALMIC GOITRE.

JAROULAY (*La Médecine Moderne*, March 3, 1894) relates a typical case of exophthalmic goitre occurring in a young lady nineteen years of age, and two other cases of goitre without exophthalmia, in all of whom the practice of exothyropexia produced excellent results. In all of the three cases the disappearance of the palpitations, the excitement, and the tremors coincided with the diminution of the goitre. In one of the cases the thyroid assumed its normal size and recovery ensued. The young lady, in whom the disease was typical, suffered a relapse, but after a second operation again experienced the same good results as she did after the first exothyropexia.\*

#### THE TREATMENT OF CHOREA.

In an interesting article DUJARDIN-BEAUMETZ (*Bulletin Génér. de Thérapeutique*, March 15, 1894) reviews the therapeutics of chorea, and then gives his personal experience in the matter. In chorea of rheumatic origin, antipyrin does good in doses of 4 grammes (60 grains) per day. According to Legroux, this medication brings about a cure in from fifteen to twenty days of treatment, this result being obtained especially in the declining period of the malady. Antipyrin does not suffice in serious cases; in these instances chloral in large quantities is the better remedy. Chloral is well borne by children. Bouchut has given it in doses of from 3 to 5 grammes (45 to 75 grains) in the twenty-four hours. Local measures, in both mild and grave cases of rheumatic chorea, are advisable, such as cold-water douches, or, better still, ether spraying along the vertebral column. In some cases massage and gymnastic exercise are of advantage, the latter being particularly indicated in the declining stages of the disease. In hysterical chorea the treatment is different, particularly when the signs of the nervous element are well established. In this form of the disorder bromide of potassium and hydrotherapy are the

\* Exothyropexia is the operation for goitre in which the gland is loosened as much as possible and brought outside the incision, where it is allowed to atrophy.—Ed.

best agents and more apt than others to bring about a cure. Bromide of potassium must be given in large doses,—that is, from 2 to 4 grammes (30 to 60 grains) a day. The following solution is recommended :

R Bromide of potassium, 15 grammes (℥iv);  
Water, 250 grammes (℥lxxvi). M.

Sig.—2 to 4 spoonfuls a day in a little black coffee.

Sometimes it is necessary to associate a tonic. If chlorosis exists, as in the case of young girls, arsenic is given at the same time. Hydrotherapy is a necessary adjuvant, since it acts not only as a stimulant to the nervous system, but also combats successfully the depression caused by the prolonged administration of the bromides, especially the potassium salt. This measure is best applied in the form of a cold douche, first over the vertebral column, and, finally, in the form of a warm douche over the lower extremities. When the nervous excitement is extreme, lukewarm douches are to be employed at the beginning of this treatment, the temperature of the water being gradually diminished. In some cases the disease is so intense as to make the douches difficult of application; in such instances the body should be wrapped with wet sheets for a period of from ten to fifteen seconds, after which the patient is to be covered with warm clothing. Massage and gymnastics may also be applied in suitable cases, taking the same precautions referred to in speaking of the treatment of rheumatic chorea. In the paralytic form of the disease the bromides should be avoided. In these cases wrapping the body in wet sheets is the best measure to be employed, and in regard to the use of drugs, hyoscyamine, as proposed by Oulment, is but little employed now. Magnan has suggested the use of hyoscyne hypodermically. The following formula is recommended :

R Hydrochlorate of hyoscyne, .01 gramme (gr.  $\frac{1}{100}$ );  
Boiled water, 5 grammes (℥zi). M.

Sig.—1 to 2 milligrammes (gr.  $\frac{1}{100}$  to gr.  $\frac{1}{50}$ ) of the active principle for each injection.

Finally, erosions and ulcerations of the skin, which occur as inflammatory complications, should be treated with antiseptic lotions. According to Dujardin-Beaumetz, there is no specific treatment for chorea.

#### INTRAVENOUS INJECTIONS OF CORROSIVE SUBLIMATE.

At the meeting of the Eleventh International Medical Congress, in Rome, GUIDO BACELLI (*Berliner Klin. Wochenschrift*, March 26, 1894)

said that intravenous injections had been suggested by him and employed for the cure of malaria. Professor Nothnagel maintains that they are unnecessary, as subcutaneous injections can accomplish just as much without disagreeable consequences. But Bacelli's results, published in 1890, were brilliantly successful as regards the treatment of severe forms of malaria with intravenous injections of neutral salts of quinine, and they contradict Nothnagel's opinion. Since then Bacelli has experimented with corrosive sublimate given by intravenous injections for syphilis. Experiments upon animals were tried first. He then tried the new method in two cases of cerebral syphilis which had resisted cure by other methods, including inunction and hypodermic injections of mercury and iodide of potassium in large doses. The results were excellent. Other cases followed, so that now the method is employed by many Italian physicians. The solution Bacelli employs is as follows :

Hydrarg. bichlor., 1 part;  
Sodii chlor., 3 parts;  
Aq. dest., 1000 parts.

The skin is cleansed and rendered aseptic, and a syringe of the solution is injected into a vein at the elbow, back of the hand, or thigh. The veins are first made prominent by constriction. The injection must be into the lumen of the vein, otherwise pain and swelling will result. In a few minutes (five to six) mercury is excreted in the saliva. The "cure" begins with the injection of 1 milligramme of corrosive sublimate daily,—that is to say, 1 cubic centimetre of the solution (1 to 1000); then the quantity increases from 2 to 8 milligrammes (the maximum dose). For four milligrammes a two-per-cent. sublimate solution may be employed, so as to avoid the injection of too large a quantity of fluid. In exceptional cases he begins the treatment with doses of 4 to 5 milligrammes.

Bacelli calls special attention to the following points: 1. The small quantity required. 2. The possibility of overcoming many symptoms quickly,—symptoms which indicate direct blood-poisoning with the syphilitic virus. 3. The benefit and widely-distributed action upon vessel walls which are the specially-favored seat of syphilitic alterations.

Bacelli also employs sublimate injections for the cure of echinococcus cysts. The cyst is punctured and about thirty cubic centimetres of the fluid withdrawn through a trocar; 20 cubic centimetres of one-per-mille sublimate solution are then injected, the trocar withdrawn

and a dressing applied. In five days the patient is dismissed cured. The parasite is killed, and the subjective and objective symptoms subside by degrees.

#### TREATMENT OF TYPHOID FEVER WITH LACTOPHENIN.

Lactophenin is soluble in water; it forms a crystalline powder of a slightly bitter, not unpleasant, taste. It has been tried successfully in the treatment of a variety of disorders. PROFESSOR R. VON JAKSCH (*Centralblatt für Innere Medicin*, March 17, 1894) reports its use in eighteen cases of typhoid fever. Among these were cases with a temperature remaining for days above 104° F., great clouding of the senses, and extreme prostration of the strength; also cases with severe symptoms on the part of the kidneys and some with severe hypostatic pneumonia.

He is quite willing to admit the possibility of chance in these favorable results; but, aside from the favorable results, there were other advantages observed at the bedside which distinguished this from other antipyretics and sedatives. The dose was 7 to 15 grains lactophenin, given in starch capsules. Just according to the antipyretic and quieting action produced in each case, this dose can be repeated during the day to as much as would amount to 6 grammes a day.

Von Jaksch has thus far observed no harmful action from this remedy. Besides these eighteen cases of typhoid fever, he has also used it in thirty-three cases of the most varied diseases, including polyarthritis, influenza, scarlatina, sepsis, etc. Here, also, far more than a thousand separate observations showed neither harmful action nor any unpleasant one to the patients. Dr. Riedel will report these observations at length elsewhere. In one single case, after the first dose of ½ gramme, vomiting and illness occurred; the succeeding doses caused no discomfort, and the remedy worked as well as in the other seventeen cases. Twice they observed a somewhat arrhythmic pulse. As this was not found in hundreds of other observations, it may be questioned whether it should be blamed upon the action of the lactophenin. He also adds that in neither blood nor urine were symptoms observed which would indicate an unfavorable action of the fluid.

The urine showed in the cases treated with lactophenin the para-amidophenol reaction. The lactophenin excels because the reduction of temperature is gradual and lasts for hours, and, further, the increase of temperature is not

accompanied by a rigor, even when the change of temperature is rapid. There was one exception to this.

Lactophenin has an uncommonly calming effect on the typhoid patient. Delirium vanishes, the senses become clear, and, without exception, the patients rejoice in a subjective healthfulness such as Von Jaksch has until now never observed under any other mode of treating typhoid. It was also noted that hunger soon occurred in all cases; in fact, most of them as soon as lactophenin had been given a few days, and they were speedily cured.

It is still not possible to decide how far chance played a part here, as all the cases which he had observed since using lactophenin were those rapidly cured, or how far this rapid favorable course is to be ascribed to the lactophenin.

While withholding final decision as to its absolute value, and whether in it a specific for typhoid fever has been found, Jaksch warmly commends lactophenin on the strength of these observations.

#### INTOXICATION WITH LYSOL AND CARBOLIC ACID.

That lysol, although less poisonous than other antiseptics, must be kept out of the reach of the children we are reminded by DR. FRIEDBERG (*Centralblatt für Innere Medicin*, March 3, 1894). After referring to two other cases recently reported, he tells of one which came under his care. A child one year old drank about ten grammes pure lysol. The physician called ordered warm milk, which the child drank without vomiting, and he then sent it to the hospital. Here its stomach was washed out with a pint of warm water. Then 15 grammes of a mixture of magnesia was introduced through the stomach-tube. This was followed by a second vomiting. The child could not swallow milk. It recovered rapidly, the cauterized places healing well. It was evident that only a very small amount of the lysol was absorbed, as the urine remained unchanged.

He also reports a curious case of poisoning with carbolic acid. A woman forty-one years old used, by mistake, a quart of two-and-a-half-per-cent. solution of carbolic acid as a clyster at 10 A.M. In five minutes she became unconscious. A clyster of 500 grammes of lime-water was given promptly; at first most of this was retained, then spontaneously evacuated, the patient being quite unconscious; 4 grammes of a solution of 1 part of camphor to 4 parts of olive oil were given subcutaneously. At 1 P.M.

the pulse was stronger and breathing quiet; the patient swallowed wine without awakening; another evacuation occurred; 10 grammes of a solution of sulphate of sodium (10 to 100) was given subcutaneously. At 2.30 P.M. the patient recognized her surroundings; she was very weak; the next day she was well; there was no change in the urine.

*A CASE OF PSEUDO-BILIARY COLIC WITH  
OBSTRUCTION OF THE COMMON  
DUCT. SOME ACCOUNT OF  
THE PHARMACOLOGICAL  
ACTION OF CALOMEL  
AND OLIVE OIL.*

VICTOR SCHULTZ reports at length (*Berliner Klinische Wochenschrift*, No. 6, 1894) a case of apparent biliary colic, and the observations and examinations by which he proved that there were no gall-stones present. He found that olive oil produced a marked increase in the secretion of bile, and that the favorable action of calomel on gall-stones and diseases of the bile-duct is not due to an increase in the secretion of bile, but to its disinfecting properties, which rapidly change the composition of the bile and thus diminish the abnormal irritation of the mucous membrane of the gall-bladder.

*TREATMENT OF DIABETES.*

In the *Indian Medical Gazette* for March, 1894, FERMIE writes that in treating diabetes it ought to be borne in mind that a dietetic treatment of an appropriate kind is most important, more especially in middle-aged people, and this bears out the rule of Prout, who laid it down long ago that "diet is the first and chief point to be attended to."

The diet ought to be so regulated as to prevent sugar being formed from the food, so that all sugar-forming food must be prohibited. This prohibition should be gradual and not abrupt. Its place, however, must be supplemented by assimilable oil or fat food, such as cream, cod-liver oil, butter, cheese, fat bacon, ham, and meat to any quantity, except liver.

Too much milk should not be allowed, nor should pastry, potatoes, beet-root, puddings, and farinaceous substances be allowed at all. The highly-advertised diabetic foods, if really prepared, as stated, without starch, will be very beneficial, and will supply a want long felt in filling up the gaps made by the prohibition of articles of food which long use has made almost indispensable, and renders the patient less discontented with the task set before

him and more amenable to treatment. The gluten and almond biscuits prepared for the victims of diabetes are so pleasant to the taste that invalids require no encouragement to use them. Diabetic food may also be sweetened with saccharin tabloids.

It is necessary to regulate the drink as well as the food of diabetic patients. Water should only be drunk in moderation, while chocolate, sweet ales, cider, and all sweet and sparkling wines should be forbidden; in fact, it is inadvisable to take alcohol in any form.

So far as drug treatment goes, there is none which may be termed consistently satisfactory. Codeine certainly, in combination with a strict diet, has a beneficial result. It may be given in  $\frac{1}{4}$ - or  $\frac{1}{2}$ -grain doses three times a day at first, then less frequently. Dr. Mitchell Bruce thinks that opium or its derivatives should not be used until the full effect of a strict diet has been tried; but clinical experience goes to show that codeine can and ought to be given coincident with a strict diet; one acts as an adjuvant of the other and hastens the process of cure. Professor Fraser thinks that morphine is more effective in some cases than codeine.

Salicylate of sodium is regarded with favor by some, especially in those cases where opium is contraindicated.

In treating diabetic coma, early and thorough purging with a large dose of calomel is about the best, followed by stimulants and doses of potass. acetat with digitalis every hour at first and then less frequently.

*THE MODERN TREATMENT OF DIPHTHERIA.*

FISCHER, of New York, contributes the following conclusions to the *Post-Graduate* for April, 1894:

1. Local disinfection,—careful distinct nasal antisepsis by means of naso-pharyngeal irrigation; this can be done by irrigating with warm salt water (1 drachm to the pint); the addition of bichloride of mercury (1 grain to the pint), or of borax (1 to 2 drachms), or acid salicylic (4 grains to the pint), is regarded as an improvement by some. It should be thrown with enough force to flow out the other nostril and partly by the throat. Tearing the membrane or using force will cause epistaxis, and is not advisable. Jacobi says, in his treatise on diphtheria (p. 208), "When they see benzoate of sodium destroying bacteria in a glass vessel, they take it for granted that the human system will permit of the same action as a glass vessel. Thus, benzoate of
